In this study the subject was made to *keep the tongue protruding out of his mouth* and a simultaneous and liberal application of *moist salt crystals was made to both anterior* halves of the tongue along the sides The subject was told the application could be either salt or sweet He indicated perception on each side by raising his hands off his knees both together if the perception was simultaneous or one at a time as the case may be As he took his tongue in he stated what the modality of taste was Occasionally *a patient said that it was bitter or sweet* before he perceived the salt In a normal subject in this test salt is perceived within five seconds and *simultaneously on both* sides This appears to apply even to the older subjects and to smokers Salt crystals were always used for testing since it was found that in those patients *with delayed* taste perception say to sweet was so tardy that it could be taken as no perception at all or aguesia The outside limits of what is normal could be accepted as 7 seconds and simultaneous perception One normal subject who was in a position to remonstrate with the author said after raising *both her* hands at 7 seconds that she had delayed becuase of the confusion the author had caused by saying that the application could be of salt or sweet In the *patients themselves* first of all taste perception was never simultaneous on both sides and this in itself should lead to suspicion In about *70% of cases the delay was over 20 sec* on one or both sides and at this stage the test was abandoned and recorded as over 20 sec *In 23% of cases it was over 15 sec.* In 7% of cases the perception was 12 sec or under In some of these the case may have been they were headache free at the time but in 3% of cases altogether the perception was in 3 or 4 sec and almost simul*taneous on both sides For these the explanation already advanced will not be ac*ceptable It will be seen that slight variations in the pattern of the disturbance that causes the headache and also the possibility that the cortical taste centre could be abnormally situated could be likely explanations It will also be seen that even though it was subsequently established that the in*nervation for taste was abnormal in some* cases taste perception had been delayed before their operations and returned to normal after the event This observation alone taken in conjunction with the other phenomena and observations in these patients localizes the disturbance at a cortical level

The *opinion has been expressed* that taste perception to chemical testing can be found delayed in normal individuals It will be *readily accepted that when previous studies* were done the subjects with muscle contraction headaches themselves were not excluded as subjects unsuitable for study It *will also be agreed that subjects suffering* from vascular headaches in all of whom it will be found that there is a taste delay at some time or other constitute a considerable proportion of the population In addition to this the author now knows that there are many and diverse other conditions in *which there is a taste delay* These conditions it would appear are to be categorized among those conditions which are now

called Psychogenic dizziness It will be agreed that these patients are ubiquitous and to the otologist at any rate represent a condition of uncertain aetiology In order to afford a comprehension of the author s rather unusual experience in this regard the following may be recounted About 7 years ago an adult male of 52 years complaining of what appeared to be rather minor dizziness which he wanted to be rid of was treated by avulsion of his right CT nerve His dizziness ceased and the feeble PN he exhibited in the right lateral position disappeared What is relevant here is that he had had a previous consultation with a neurologist of repute and the diagnosis had been Psychogenic dizziness This category it will be found and shown in a later communication to be so is further enlarged by patients who do not complain of dizziness but show a bilateral (direction changing) PN and what may be called neurotic or anxiety symptoms. In all these conditions if the symptoms are of a transient nature, taste perception will be found to return to normal If the disturbances are of an enduring nature such as occurring in these muscle contraction headaches taste perception can be made to return to normal as has been done even in this study in some cases and this is to be the expectation in all the cases if only the LB had been ablated without avulsing the CT as the method of treatment. This position will become acceptable from what is to follow It will be found that delay in taste perception to the test here described is always (or almost always) associated with this type of first-degree central type of PN directed away from the undermost ear It will also be found that the symptoms these patients complain of whatever they may be, have a relationship to this PN and delayed taste perception. This test for taste will certainly become useful and be found to embody an important conception perception will be found to improve as the symptoms decrease and return to normal when the latter cease Many of these patients have apparently hitherto been considered normal subjects showing delayed taste perception to chemical testing.

It appears that there is some evidence in this work that, in some cases at any rate this first-degree central type of PN associated with delayed taste perception is not a psychosomatic manifestation but a somatopsychic one and thus perhaps the ground work has been laid for the extension of the conception that some emotional disturbances may have a physical basis and that, it might be possible to manipulate this beneficially These muscle contraction headaches for example If the opinion of such authorities as Swanson (1971) is to be accepted, suffered from anxiety emotional tension and other allied manifestations and the majority of them at any rate would not agree that they had any of these features after they had been relieved of their headaches as has been done here.

Headache

With this conception regarding *vertigo* and the type of PN discussed here accepted the meeting point with the treatment of the functional headaches had to occur at some time or the other For it will be found that the vertiginous symptoms which are known to occur with all known functional headaches both muscle contraction and vascular are due to *a derangement of the mechanism defined here* In the rather exceptional circumstances of one of these headache patients refusing to admit to being dizzy it will be found that they have what has been called here latent central positional vertigo with PN Very exceptionally they do not exhibit PN during a headache, but the other relevant signs can be found In the vascular headaches these signs are to be found during the phase of a headache and in the muscle contraction headaches which really have a constant background of headache

these signs are to be found at any examination This meeting point was more likely to happen in the circumstances the author found himself in These circumstances were that during the relevant years he was the sole Otolaryngologist to what is called a Provincial Hospital in this country A few years ago such a hospital had neither Neurological nor Psychiatric services Also there was and is no referral system functioning In this situation patients with headaches sought either the author s advice or the advice of the Ophthalmologist While no doubt many little steps and almost subconscious observations led to the development described here the occasion that stands out in memory was the occaion early in 1965 when a young man with a fairly severe right sided headache of nearly one month s duration presented himself for examination He had already sought neurological ophthalmological and otolaryngological advice elsewhere The usual examinations revealed nothing an examination was made with regard to the minor vertiginous symptoms he admitted to having When it was found that they were due to the mechanism discussed here he was offered a minor otological procedure with a possibility of being relieved of his trouble This in his distress he did accept On the next morning his right CT nerve was avulsed in the afternoon he was transformed—according to him he had not even a vestige of a headache nor did it recur subsequently After this all headache patients seeking treatment were examined in the manner to be described and a minor otological procedure offered and with increasing confidence a cure was also guaranteed Many accepted and the type of headaches that presented were the spontaneously occurring muscle contraction headaches In early 1966 it was decided to study this series presented here and follow up the cases adequately It would appear that vascular headaches are not very common in this country and so it came about that it was the muscle contraction headaches that were initially studied

Composite Case History

The patients were usually young adults or adolescents with a history of recurrent and troublesome headaches of many years duration The headaches were either bilateral and diffuse or unilateral The location was usually fronto-temporal though sometimes there was an ache towards the back of the head in addition The usual pattern was that of 3 headaches a week lasting about 2–3 hours Strain and fatigue of working or travelling especially in the sun was often alleged to bring on the headache Remissions were known but never of more than 2–3 weeks Some said that the headache was really constant In most of them dizziness accompanied the headache and was noticeable when the headache was severe In 2 or 3 the dizziness was nearly as troublesome as the headache Two said that they had no dizziness at all In nearly half the patients the headache was accompanied by a low pitched tinnitus either in one or both ears As an after thought enquiry was made and it was found that tinnitus reached its maximum intensity with the headache and ceased when the headache left Even in this early study and because it was spontaneously mentioned by them there had been excessive sweating in 5 patients Two had spontaneously mentioned lack of concentration and defective memory among their complaints A fair number had complained of intermittent fullness in the ears and 6 had complained of intermittent itching Drowsi

ness was reported by 4 patients Few patients had nausea with their headaches and fewer still actually vomited at the height of their headache and this not always so Enquiry had been made about travel and reading and some patients had complaints to make in this regard and these will be referred to in what is to follow In a few lacrimation also occurred especially during the headaches and this was provoked by reading or looking at the sun or any bright light Enquiry was not made into their emotional state since this appeared to be fraught with difficulties It was of course noticed that a few patients looked visibly anxious or depressed before their operations

Material

The 100 patients came from all walks of life They were usually young adults or adolescents The average duration of their complaints was 4 years and 10 months The longest history was 30 years and the shortest 6 months in a student who said his studies were affected by the headaches There were 39 males and 61 females The oldest patient was 72 years old and the youngest was 11 and he alleged a moderately severe head injury preceded and caused the headaches In 48 the headaches were bilateral and diffuse In 52 the headache was unilateral on one or the other side

Examination

PN

The patient was made to lie on a bed in the right lateral and left lateral positions and made to look up at the roof with extreme deviation of the eyes The presence or absence of PN was noted. The results of examination for spontaneous nystagmus has been mentioned earlier The PN was an immediate brisk, horizontal non-paroxysmal non-fatigable first-degree nystagmus, directed away from the undermost ear In 47 cases the PN was bilateral (direction changing with change of position of the head) and in 53 the PN was unilateral (direction fixed) Thus only one case was an exception to the rule that in unilateral headaches the PN was unilateral and bilateral in diffuse headaches The PN was always on the side of the headache (side of PN means the side of the lateral position in which the PN is seen this is the same side as the side of the headache) This is a very satisfactory correlation The one exception of a patient with diffuse headache with unilateral PN was asked about his headache months after the operation when this discrepancy was discovered he did not alter his story but actually he said that he had forgotten. It may be mentioned that the preliminary examination for PN was made by merely pushing the patient's head backwards and to each side in turn in the clinic chair This slap dash method is useful when many examinations for PN are made in a busy clinic In this series it was not found that the neck reflexes had modified the PN even in a single case In some cases the PN was not brisk, then perhaps subsequent examinations helped It will be found that the PN can vary in briskness from examination to examination and appears to have a correlation

these signs are to be found at any examination This meeting point was more likely to happen in the circumstances the author found himself in These circumstances were that during the relevant years he was the sole Otolaryngologist to what is called a Provincial Hospital in this country A few years ago such a hospital had neither Neurological nor Psychiatric services Also there was and is no referral system functioning In this situation patients with headaches sought either the author s advice or the advice of the Ophthalmologist While no doubt many little steps and almost subconscious observations led to the development described here the occasion that stands out in memory was the occaion early in 1965 when a young man with a fairly severe right sided headache of nearly one month s duration presented himself for examination He had already sought neurological ophthalmological and otolaryngological advice elsewhere The usual examinations revealed nothing an examination was made with regard to the minor vertiginous symptoms he admitted to having When it was found that they were due to the mechanism discussed here he was offered a minor otological procedure with a possibility of being relieved of his trouble This in his distress he did accept On the next morning his right CT nerve was avulsed in the afternoon he was transformed—according to him he had not even a vestige of a headache nor did it recur subsequently After this all headache patients seeking treatment were examined in the manner to be described and a minor otological procedure offered and with increasing confidence, a cure was also guaranteed Many accepted and the type of headaches that presented were the spontaneously occurring muscle contraction headaches In early 1966 it was decided to study this series presented here and follow up the cases adequately It would appear that vascular headaches are not very common in this country and so it came about that it was the muscle contraction headaches that were initially studied

Composite Case History

The patients were usually young adults or adolescents with a history of recurrent and troublesome headaches of many years duration The headaches were either bilateral and diffuse or unilateral The location was usually fronto-temporal though sometimes there was an ache towards the back of the head in addition The usual pattern was that of 3 headaches a week lasting about 2–3 hours Strain and fatigue of working or travelling especially in the sun was often alleged to bring on the headache. Remissions were known but never of more than 2–3 weeks Some said that the headache was really constant In most of them dizziness accompanied the headache and was noticeable when the headache was severe In 2 or 3 the dizziness was nearly as troublesome as the headache Two said that they had no dizziness at all In nearly half the patients the headache was accompanied by a low pitched tinnitus either in one or both ears As an after thought enquiry was made and it was found that tinnitus reached its maximum intensity with the headache and ceased when the headache left Even in this early study and because it was spontaneously mentioned by them there had been excessive sweating in 5 patients Two had spontaneously mentioned lack of concentration and defective memory among ther [illegible]m plaints A fair number had complained of intermittent fullness in the ears and [illegible] had complained of intermittent itching Drowsi

small minority It would appear that the actual incidence of unilateral trouble is about 20 to 25% In the early days when a bilateral operation was suggested patients tended not to accept, and when the persuasive after all it is to be a tiny operation in one ear was offered the patient tended to accept. Even today middle-class patients who do not know the author appear to be prejudiced against the procedure however troubled they are they apparently know enough to know that headaches cannot be cured through the ear and that an ear operation particularly a bilateral one could make them deaf The operations were usually done under local anaesthetic and moderate sedation. A reasonable and mature 16-year old is usually cooperative Those under this age were given a general anaesthetic The CT was first lowered rather forcibly and even stretched and the medial aspect of the proximal end was examined At 16 such examinations a knot was seen On seeing this the assistant examined the eyes for a first degree nystagmus directed away from the operated ear and this was always present (Nystagmus was sought prior to the operation and was not present there has occasionally been a twitch only with the drugs used for sedation in this study they were Chlorpromazine Promezathine and Pethidine) In one bilateral case this knot was seen in both ears and in 2 unilateral cases in the operated ears Thus in these 3 cases the CTs were spared and they were cured These cases constitute the evidence that the essential part of the operation is the successful ablation of the LB or LBs

Results

There were 4 recurrences, and since the symptoms of their recurrence were eliminated by a second operation based on the conception embodied here a 100% successful result is claimed and is valid There was a satisfactory follow-up of nearly 2 years in the earlier cases and 1 year 7 months in the later cases of this series. After this the author moved to a larger older and better known hospital in the capital city 70 miles away Thereafter the follow-up was largely a negative one and so if necessary no claim to follow-up will be made at all for this latter period The patients had been instructed to contact the author by letter in the first instance if they developed any recurrent headaches. Since no intermittent contact was maintained with them during the intervening years it has not been possible to contact all of them by letter a few months ago However it can be stated that there is no known case of a recurrence either in this series or in any other series This includes cases treated in 1965 8 years ago some of whom are in contact with the author and are all well If recurrences occur they are of the nature to be described and it will be agreed that they would come to the notice of the author It will be seen that such recurrences readily agree to a second operation.

One case who had a unilateral operation in her right ear in early 1966 had contacted the author with recurrent headaches which were *mainly* left-sided which had occurred from about April this year She has recently had only her left LB ablated and she is now well Another patient a male of 31 years at the time of a unilateral operation in February 1966 remained well till early 1970 when he got what he calls an attack of collapse he subsequently had two further attacks one in 1970 and another in 1971 and has since remained free of them. Even after all these years he remembers that his headaches had been very severe He

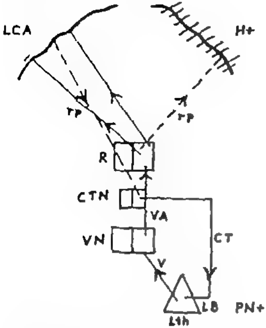

Fig 3 H+ PN+ Left-sided headache and PN Right irritable LCA. *Lth* labyrinth *V* vestibular nerve *VN* vestibular nucleus, *VA* vestibular afferents to ipsilateral *R* reticular area *rp* reticular-cortical projections (major contralateral minor ipsilateral). Connection of LCA to CTN (CT nucleus) CT and LB shown.

elaboration here The observations of Carmichael et al are well known and accepted as proven and it will be seen their results completely confirm the author s conception and postulation There is then an irritable LCA in the middle of the superior temporal gyrus and it is an effector area Directional sensitivity is not merely a prolonged sensation of vertigo but is a prolonged nystagmic movement of the eyes It cannot be contended that the sensory vestibular projection area does this It is known that nystagmus is the exception rather than the rule in vertigo i e there is a sensation of turning or unsteadiness without nystagmic eye *movement* why *should* a prolonged vertiginous sensation produce eye movement here?

Since one part of the *postulation* (the (LCA) is confirmed it is reasonable that the rest of the postulation is also *correct* and the effect is produced through the LB Further the conception set out here completely conforms to the requirements so ably anticipated by Carmichael et al (1956) of the neurological mechanism that can explain the phenomenon of directional preponderance or directional sensitivity of caloric nystagmus Here the tonus element has been identified its brain stem representation as required by them is at a different level from the vestibular representation They too envisaged a connection to the opposite temporal cortex (Fig 3) Here further is an explanation and a situation in which the tonus element is hyperactive on one or both sides When it is hyperactive on one side or more so on one side than the other *directional sensitivity* results How it can be hyperactive in other situations of *vertigo* will be touched upon and explained briefly Here then a hypothesis because *it* is corroborated in the manner described above has become acceptable as a scientific fact The LB is an integral part of the whole conception so there has to be and there is an LB It is evident that proof that when the LB is ablated this directional sensitivity is abolished (or markedly decreased) will readily be forthcoming Penfield (1954) stimulating the parietal *lobe produced nystagmus an* effector phenomenon so there has to be an effector area close to his point of stimulation

Treatment

At the time this work was done the method used to break the LB was to avulse the CT nerve with a fine hook *as close to the* annulus as possible There were 47 bilateral operations and 53 unilateral operations This series represents a rather high percentage *of unilateral cases In a similar group re*cently treated the unilateral cases are a

caused blurring: one boy said there were occasions when he had diplopia while reading. All these symptoms ceased at operation. As far as the author knows there is no awareness of the fact that the disturbance which produces the PN of the type described here affects the vestibulo-visual fixation mechanism and leads to difficulty with continued reading.

Lacrimation

Lacrimation occurs sometimes as a result of reading or on looking at a bright light or at the sun, in one case the lacrimation was spontaneous. These too ceased

Lack of concentration, defective memory drowsiness

These, as said before, occur as symptoms in the recorded history of a very few patients in this series since they were not symptoms for the presence of which enquiry was made. Later however and in later series enquiry showed these symptoms to occur in varying degree in quite a high proportion of patients with these headaches. It is possible that if careful inquiry were made the figures might be as high as 60% particularly for drowsiness and lack of concentration, and what is more the symptoms cease with their operations

Excessive sweating

This also occurs more frequently than has found representation in this series. Very occasionally the hyperhydrosis affects the palms and soles making manual work difficult. In one case with this troublesome symptom, the anticonvulsant Dilantin produced noticeable improvement, this when confirmed will lend support to the contentions the author will make here that these features are all manifestations of a minor epileptic process. At operation all excessive sweating ceases

Fulness of the ear(s) and inexplicable itching

Intermittent fulness of the ear(s) was fairly often reported in this series since inquiry was always made about the hearing. Itching was infrequently reported but it is now evident that if it is inquired into minor itching is a fairly frequent accompaniment whenever there is hyperactivity of the LB mechanism. It is also now known that patients presenting with this symptom only and when nothing exceptional is found in the meatus have delayed taste (frequently over 20 seconds) and feeble PN. It represents a paraesthesia, and the implication also follows that the CT nerve gives off a branch to the meatus; this latter observation has been made before

Recurrences

(A) Three cases after unilateral operation presented with a recurrence 2 weeks, 4 months and 15 months after the interference. The headache had shifted to the other side; in 2 who had had tinnitus this too had changed sides and so too had the PN and the sway in Romberg's test. Two had their CT nerves avulsed and one had only the LB broken and they have remained well since. All 3 were caloriized in the manner described before their second operation also and though all 3 said that it was the second ear when tested which had made them more giddy the marked directional sensitivity seen in a newly presenting *unilateral* case was nevertheless not found; there appears to be a reason for this though it cannot be discussed here nor is it necessary

(B) One patient who had a bilateral operation which had consisted of an avulsion of the CT nerve on the left and a successful breaking of the LB on the right, presented

was also one of the patients who had vomited with travel In his case a journey of over 10 miles would have brought this about. His operation had been a right LB ablation only and after it he had been completely free of headaches and also of any discomfort with travel After his attacks of collapse he is giddy with travel but not giddy otherwise He is apparently not very concerned about this since nausea does not occur except with very long journeys When he happened to mention this to the author in the middle of this year he was asked why he had not reported all this earlier and he replied that he had not thought that collapse concerned the author who had operated for headache His attacks seem to have been acute vertigo leading rapidly to a fall in blood pressure.

Other Results

Tinnitus

In 46 cases there had been a tinnitus and in all of them the tinnitus ceased immediately Only in one case a male of 43 years who had a bilateral operation and a bilateral tinnitus the tinnitus persisted in one ear It was however softer and of a higher pitch This patient was found to have early presbyacusis Though it was not inquired into at the time of this study and since it is now known and would constitute useful information it may be stated that the tinnitus associated with the LB mechanism is always a low pitched one corresponding to the 125 cps tone of the PT audiometer The tinnitus is not a constant whine but an interrupted hum – hum – hum Occasionally a patient says that though it corresponds to the 125 cps tone it is a ho – ho – ho sound Very very exceptionally a patient says the sound is lower pitched than that and likens it to falling rain and this corresponds to a tone of 64 cps One patient who had a tinnitus in this series in one ear a week after operation said the sound had recurred and she was found to have a retracted drum this cleared up It is now known that such patients will liken the sound to the sound of surf on a tropical beach and this would apparently correspond to a tone of 32 cps Three patients who had unilateral PN had occasional tinnitus in the other ear this too ceased with the unilateral operation

Travel

Six patients had said that they had symptoms of motion sickness and vomited on the limited travel they were wont to undertake Such travel was only of the order of 10 to 20 miles The adjoining country was hilly and the roads winding

This work when repeated in the coastal plains discloses about 3 to 4 patients in every 100 who actually vomit with limited travel These patients after their operations become totally changed for the better in their reaction to travel There is no equivocation about this A few patients in this series said they got sick headaches with travel many said they tended to get a headache with travel Three said they became a little giddy with travel and tended to be unsteady when they got off the bus Many said they had no discomfort with travel In those who had any symptoms such symptoms ceased at operation

Reading

Since most of the patients were peasants and labourers not many seriously complained of any difficulty with reading Among those who appeared to read to any extent (the complaints were thus commoner among students) there were instances of the letters blurring become squiggly and some said the lacrimation that occurred

acceptable upper limit of normal) at least, and to improve to 5 sec within a few days. This also happened with the 16 CTs that were spared here return of taste took a varying number of weeks as is to be expected. When in future studies only the LBs are ablated this will be found to be so in every case. The taste delay (before the operation) as said before is usually over 20 sec. When the taste delay which improves dramatically is considered along with its association with the muscle contraction headache, which also has been cured, it will become acceptable and evident that the disturbance must have been epileptiform and must have occurred in the cerebral cortex. No other pathology or location is *feasible* particularly when the other associated symptoms are taken into consideration. With these evidence of another disturbance occurs in such cases and that is a central type of first-degree PN. All that can be acceptably said at present with regard to PN is that it is evidence of a disordered or pathological link somewhere in the vestibular complex which becomes *manifest* in the activation process of a positional test. This PN also must have a cortical origin because of the invariable association described here. Nobody has suggested or would suggest that this PN is due to a disorder in the vestibular projection (sensory) area in the cortex. By this reasoning alone there must be an *effector* LCA. There is already substantial evidence in this study of its existence and of its location. *Taste* representation in the cortex Penfield & Jasper (1954) say is at the bottom of the post central gyrus (Fig. 2) deep in the Sylvian fissure on the superior bank above the insula and probably extending onto the insula. The location of the motor area which when affected by an epileptiform process can produce sustained muscle contraction of the scalp muscles is well known and is very nearby. The LCA is also nearby and has to be nearby on the superior temporal gyrus. The auditory sensory area is mainly in Heschl's gyrus (anterior transverse gyrus on the superior surface of the temporal lobe) on the inferior bank of the Sylvian fissure. Penfield & Jasper (1954) also say that there is evidence of vestibular representation adjacent to (and posterior to) Heschl's gyrus within the Sylvian fissure. Though it is not necessary for the purposes of the author's thesis, it is suggested however and is likely to be accepted as being in fact so (from the evidence that emerges here) that the LCA extends into the Sylvian fissure onto the inferior bank and onto the surface of the insula. Davis & Davis (1964) for instance say that the cytoarchitecture of the posterior part of the insula resembles that of the temporal cortex while that of the anterior part does not. The taste area and the LCA must be contiguous. The author wishes to emphasize this and it will be found to be so that this central type of first-degree PN is always associated with delayed *taste* perception and is to be found in many vague conditions which must be called psychogenic. Nature has ordained this to be *so*. Nature always works to an approved pattern. *It will be found in all* nausea there is PN and delayed taste perception. In mild nausea the PN will be feeble and taste delay will only be *of the order of 3* or *4* seconds but both will disappear when the nausea ceases. This arrangement will put an animal instinctively off its food when there is nausea, and this is beneficial particularly if the cause is alimentary. It will be seen that for perhaps a good reason nature has ordained *that this LCA* is easily disturbed. It is evident then how the various disturbances (Fig. 2) that accompany these headaches occur. To explain the sweating lacrimation, *etc.* reference is made to *Van Buren (1958)* who says that the autonomic representation in the temporal cortex *is to be found in* the insula and mesial temporal region etc. The superior temporal cortex and the insula slope onto the mesial tempo-

after 8 weeks with a left sided headache A left PN and a sway to the left in Romberg s test was found The intact LB in the left ear was successfully ablated (a nystagmus followed) in the manner to be described and she has remained well since

Criticism

Bilateral avulsion of the CT nerves naturally affects taste perception but appeared to be satisfactorily adjusted to A more serious consequence is a dry mouth Curiously only one patient complained of this The author however usually avoided discussing any disabilities that resulted from such an operation So this may not give a true overall picture

Alternative Technique

If the CT nerve is only gently lowered (this is done in order to locate its proximal end) the knot that was described earlier will not be seen The proximal end of the nerve is in the vertical plane exactly midway between the stapedius tendon and the round window Occasionally it may be slightly higher or slightly lower than this but it is always below the tendon It is of course posterior to the incudo-stapedial articulation The posterior wall of the middle ear is now scraped fairly firmly with 3 or 4 vertical strokes from above downwards by introducing an angled instrument with a flat blade below the nerve The instrument the author uses is Rosen s annulus ring curette It would appear preferable that the instrument had a cutting edge With experience the CT need not even be lowered Unnecessary curettage to find the nerve appears undesirable since it may damage the nerve

Occasionally the ablation of the LB has been done without seeing the CT Sometimes the only structure to be seen without undue curettage is the round window Successful ablation of the LB always produces an immediate brisk nystagmus There should be no difficulty in successfully ablating the branch under general anaesthesia, though seeing the nystagmus is satisfying Very very occasionally there is no nystagmus or merely a sort of wandering of the eyes on deviation Even in these rare instances a nystagmus develops later on though it may be feeble It is useful to mention that if a barbiturate such as Nembutal is used as a sedative there may be a nystagmus before the operation There is no reason why the incudo-stapedial articulation should be disturbed by this procedure Occasionally a mild facial palsy develops which always clears up in an hour or two

Discussion

It was found in this study in 19 instances where the nerve supply had evidently been abnormal that with the avulsion of the CT taste perception had returned to normal i e to within 5 sec the next day in every single case If not 5 seconds then to 7 sec (th

acceptable upper limit of normal) at least and to improve to 5 sec within a few days This also happened with the 16 CTs that were spared here return of taste took a varying number of weeks as is to be expected When in future studies only the LBs are ablated this will be found to be so in every case The taste delay (before the operation) as said before is usually over 20 sec When the taste delay which improves dramatically is considered along with its association with the muscle contraction headache, which also has been cured it will become acceptable and evident that the disturbance must have been epileptiform and must have occurred in the cerebral cortex No other pathology or location is feasible particularly when the other associated symptoms are taken into consideration. With these evidence of another disturbance occurs in such cases and that is a central type of first-degree PN All that can be acceptably said at present with *regard to PN is that it is evidence of a* disordered or pathological link somewhere in the vestibular complex which becomes manifest in the activation *process of a posi*tional test This PN also must have a cortical origin because of the invariable association described here Nobody has suggested or would suggest that this PN is due to a disorder in the vestibular *projection* (sensory) area in the cortex By this *reasoning* alone there must be an effector LCA There is already substantial evidence in this study of its existence and of its location Taste representation in the cortex Penfield & Jasper (1954) say is at the bottom of the post central gyrus (Fig. 2) deep in the Sylvian fissure on the superior bank above the insula and probably extending onto the insula. The location of the motor area which when affected by an epileptiform process can produce sustained muscle contraction of the scalp muscles is well known and is very nearby The LCA is also nearby *and has* to be nearby on the superior temporal gyrus The auditory sensory area is mainly in Heschl s gyrus (anterior transverse gyrus on the superior surface of the temporal lobe) on the inferior bank of the Sylvian fissure. Penfield & Jasper (1954) also say that there is evidence of vestibular representation adjacent to (and posterior to) Heschl s gyrus within the Sylvian fissure. Though it is not necessary for the purposes of the author s thesis it is suggested, however and is likely to be accepted as being in fact so (from the evidence that emerges here) that the LCA extends into the Sylvian fissure onto the inferior bank and onto the surface of the insula Davis & Davis (1964) for instance say that the cytoarchitecture of the posterior part of the insula resembles that of the temporal cortex while that of the anterior part does not. The taste area and the LCA must be contiguous The author wishes to emphasize this and it will be found to be so that this central type of first-degree PN is always associated with delayed taste perception and is to be found in many vague conditions which must be called psychogenic. Nature has ordained this to be so Nature always works to an approved pattern. *It will be found in all nausea there is PN and delayed taste* perception. In mild nausea the PN will be feeble and taste delay will *only* be of the order of 3 or 4 seconds but both will disappear when the nausea ceases *This* arrangement will put an animal *instinctively* off its food when there is nausea, and this is beneficial particularly if the cause is alimentary It will be seen that *for perhaps* a good reason nature has ordained that this LCA is easily disturbed It is *evident* then how the various disturbances (Fig 2) that accompany these headaches occur To explain the sweating lacrimation, etc. reference is made to Van Buren (1958) who says *that* the autonomic representation *in the temporal* cortex is to be found in the insula and *mesial* temporal region etc. The superior temporal cortex and the *insula* slope onto the mesial tempo-

ral cortex Penfield (1954) makes reference to his findings that disturbance in the insula can lead to nausea and other alimentary disturbances The itching that attention has been drawn to here (and the suggestion is made that it should always be inquired for) represents a disturbance in the sensory cortex adjacent to the taste area Intermittent *fulness of the ears and the tinnitus are* readily explained The headache itself is due *to disturbance in the bottom of the motor* area which controls the muscles of the head

To explain how the headaches commence and how they can be successfully treated instead of quoting experimental and other evidence here reference will be made to a comparable phenomenon for which an explanation is available and a reference may be made to the work that embodies this Behrman & Wyke (1958) clinically distinguish one variety of vertiginous seizures Vesti*bulogenic seizures they say are a type of* reflex epilepsy A spontaneously occurring severe labyrinthine disturbance sets up disorderly impulses in the vestibular afferent pathways on one side (Fig 3) and because the disturbance is severe a disturbance in both reticular areas in the brain stem results Each reticular area has a major connection to the contralateral cortex cerebri and a minor one to the ipsilateral cortex In this condition a massive bombardment *of the* cortex on both sides results bringing about *the ictal discharge and the seizure* There *is further evidence in this thesis of a general* and corroborative nature that this LCA is *easily disturbed Schiller & Hedberg (1960)* found PN in all their cases of lesion of the parieto-temporal lobe (both in epilepsy and tumour) The author (who works in a hospital for adults) *happened* to examine 3 children between the ages of 10 and 13 years during the past 2 months One his own son because he complained of a headache for no reason *another his dental colleague s* son who for the past month had been making *involuntary* expirat n gasps frequently (this is an example of a vague symptom which occurs with this PN) and found they had bilateral PN and taste delay of over 20 sec on both sides Another girl casually examined for vague throat *symptoms had* left sided PN and taste R 11 L over 20 sec *None of them were giddy nor unsteady* at all in Romberg s test Evidence that these *signs are to be found* in otherwise normal children will be readily forthcoming Two of *these children described had developed* an aversion to travel Jongkees (1960) refers to the fact that *PN often* occurs without giddiness and recognition of this is necessary *for the purpose of the author s thesis* Considering an unilateral left sided headache with a left PN the disturbance *is then in the right* LCA (Fig 3) In a subject such as the girl described above if she is so predisposed a *continuing disturbance of this nature stimu*lates the labyrinth abnormally through the *LB and a minor vestibulogenic effect results* Since it is minor the hypothesis is advanced *that only the ipsilateral* (left) reticular area is disturbed and this brings about increasing disturbance in the right LCA only initially sufficient one day to cause spread to the surrounding contiguous area of the cortex Later the pattern of recurrent headaches becomes established

This concept that the vestibulogenic feed*back is initially to the* LCA and that dizziness only occurs when there is spread to the vestibular (sensory) projection area is a new one and perhaps an important one The corroboration arising from Jongkees observation *referred* to above emphasizes its validity Later the pattern of recurrent headaches *becomes* established The pattern is well known and has been described here This keeps on *recurring and in those who* have a constant dull headache too there is a *constant involvement of the scalp muscle* motor area nearby The disturbance waxes and wanes *spreading and receding* as all epileptic processes are known *to do for* reasons which are *not clear* The process

continues and even old age may not bring relief (Graham 1963) What can be done about it? It will be evident that if the abnormal excessive vestibulogenic feed back is abolished by ablating the left LB in a left sided headache some benefit should accrue In this study this has been done and the headache ceased it will be seen that it should not thereafter recur either Since with this ablation the disturbance in the right LCA either subsides completely or sufficiently (see Recurrence B) that it no longer spreads hence thereafter there is no recurrence of headache and its accompanying symptoms whatever they may be from tinnitus to drowsiness and defective memory and nausea and vomiting. There must also be a good reason why the tinnitus is always low-pitched but this will not be discussed here. Taste perception should also return to normal and it will be found (and has been found even in this study) to return to normal i e perception in 5 sec in the test described Behrman & Wyke have drawn attention to the fact that each reticular area has a minor connection to the ipsilateral cortex Thus any evidence of a minor disturbance on the opposite side should also subside This was found to be the case. The taste finding in a unilateral case typically is R 13 L over 20 sec before operation and on the morning after the finding is R 5 secs L negative If the innervation had been abnormal the finding would be R and L 5 sec simultaneous. This explains why 3 unilateral cases had bilateral tinnitus and why there could be bilateral itching and why the symptoms in both ears cease with a unilateral operation The explanation is complete and by this very completeness by the method of science lends strong support to the entire concept. The findings in one case in this series provide further support A girl of 19 years with right-sided headache of 5 years duration had for 3 years or so two other features About once a month with her headaches and dizziness she used to fall on the floor and be pale and still with clenched teeth unconscious for $\frac{1}{2}$ an hour or so Also with the headache and giddiness she would have quite severe right sided collcky abdominal pain about twice a week. This pain could last one day some times though usually it lasted a few hours only After investigations her appendix had been removed a year previously without affording her relief After her ear operation both the akinetic seizures and her abdominal pain ceased and did not recur The latter took about 2 weeks to subside completely It is well known that both these are epileptic phenomena. Penfield (1954) has done temporal lobectomy and insulectomy for severe alimentary seizures Akinetic seizures will be found to accompany these headaches in about 3% of cases and severe inexplicable abdominal pain in 2% and less severe pain and flatulence to the extent of about 5 to 6% in all These will usually disappear with their ear operations or if not will be found to be greatly reduced

EEG was not done in the case referred to and was only done in 3 chronic cases and was found to be normal Perhaps activation procedures prior to EEG may reveal abnormalities in some cases as has already been found in migraine Blau (1971) refers to this and says the concept that migraine is epileptic is an old one

Further support for the entire conception is afforded by the following conditions and an explanation of their mechanism of production on the basis of this conception is enlightening that headache is often associated with vertigo is well known. Its association with Menière s disease has been referred to by Colman (1971) It is clear now why this happens In severe vertigo e.g. severe acute Menière what may be called collapse occurs The patient is found to be pale and cold and to look anxious and depressed there is sweating and salivation and even hyperventilation there is pain in the head nausea and vomit

ing The pulse is slow and the blood pressure low Colman (1971) *says that this is a* vagal effect It will be seen that the symptoms and signs are both parasympathetic and sympathetic *It is now clear how severe* vertigo through a vestibulogenic effect and feed back through the LBs leading to a circuit generating hyperactivity causes spreading excitation from the LCAs to the area of autonomic representation thus giving these features The conception of Behrman & Wyke *explains how in severe vertigo* both reticular areas become activated thus *leading to increased excitation in both LCAs* which may not be equal If the LB mechanism is very hyperactive spontaneous nystagmus can also occur (cf nystagmus on LB ablation) This excessive cortical activity leads in the rare predisposed subject to a seizure (Behrman & Wyke) and also in rare instances to unconsciousness alone (Golding Wood 1960) *This also explains why PN* has been found in Menière s disease why *directional* preponderance or *sensitivity* has been found in the caloric tests and why the nystagmus can be unpredictable and found to change direction (Colman 1971) and also why the sensation of turning or of falling is unpredictable and can be to either side (Golding Wood 1960) An explanation for these features has been difficult hitherto *Only the feature of excessive salivation has* not been explained here Penfield (1954) says the cortical area for salivation is at the bottom of the motor area nearby Arulpragasam (1967) found PN in the syndrome of vertigo and salivary gland enlargement and in recurrent parotitis These conditions he stated were due to excessive secretory activity engendered by an *epileptiform* process It is now known that in these conditions there is a taste delay thus placing the disturbance in the cortical area under consideration here It appears that hyperventilation can also be explained but will not be undertaken *What is less well documented is* the fact that in moderately severe vertigo a rise of blood pressure will be found Any *family physician will confirm that this is a* common occurrence His explanation for this will differ from what is advanced here It is *clear that spreading excitation in the LCAs* in moderately severe vertigo will bring the temporary elevation of blood pressure that has been so commonly observed *It is the* vertigo that brings about such elevation and not the elevated blood pressure the vertigo as it is now believed to be *the explanation* *Van Buren (1958) studying* temporal lobe epilepsy and the autonomic concomitants of *ictal automatism* found rise of *blood* pressure tachycardia lacrimation retching flushing of the face swallowing and other changes relevant here. A recorded fall in blood pressure did not occur among his cases but he gives an explanation of why this may not have been recorded He came to the conclusion that there is probably *spatial separation of the representation of* autonomic function in the temporal cortex *A delay in taste* perception *must occur in* the situations discussed here

Wood & Graybiel (1973) say the symptoms of motion sickness vary with the individual although in a given individual the same pattern of signs and symptoms will follow repeatedly They may include any or all of the following drowsiness yawning salivation swallowing hyperventilation headache and flushing followed by pallor of increasing intensity Cold sweat on the forehead underarms hands and around the mouth is frequently observed Increasing nausea may lead to vomiting *To this the* author adds minor itching of the ears and *fulness of the ears during* the nausea In nausea there is a bitter taste in the mouth and it will not be surprising if taste perception will be found delayed that there is a PN in acceleration deceleration and stoppage of movement is well known How the disordered vestibular afferents in motion *bring about an* excitation of the LCAs and the neuronic *circuit described here* will

further stimulate the labyrinths and through a vestibulogenic effect bring about spreading excitation from the LCAs is clear It will be noticed that these symptoms and signs strongly resemble those found in the muscle contraction headaches and the state of collapse of a severe Menière s attack If as in the headaches the neuronic circuit is broken, relief should follow This can be achieved in two ways one is to destroy the labyrinth or the afferents on both sides and that this will bring relief has already been found (e g. deaf mutes with defective labyrinths react differently when tested Wood & *Graybiel 1973)* The other way is to ablate the LBs There is some evidence in this study itself that this will prove beneficial Since fresh light on the subject of motion sickness is eagerly being sought particularly at the present time the following experimental evidence can usefully be juxtaposed since it will be found to support the views expressed here Jongkees (1960) citing the experimental work of Fernandez et al says that the lesions of the nodulus cerebelli in the rabbit give PN which disappeared when the labyrinth was destroyed Keel & Neil (1966) record that electrical stimulation of the flocculonodular *lobe of the cerebellum* brings about evoked potentials in the ecto-sylvian gyri of the cat and the dog, and comment on how extensive the vestibular representation in the cortex is (This in itself is evidence for the LCA and its *location*, since the cerebellum is not known to have connections with sensory areas *of the cortex* Its function is to suitably modify corticofugal effector effects.) These authors also state that the auditory sensory area in these animals is in the ecto-sylvian gyri Hence it follows that the ecto-sylvian gyri *in these animals correspond* to the LCA and Heschl s gyrus in man. Then they say that if the nodulus cerebelli is removed *in a dog*, the animal cannot thereafter be made to become motion sick.

It would appear that in all nausea there is a disturbance in the LBs This is stated in order to suggest that the original function of the LBs in phylogeny was to trigger off nausea and vomiting. If this mechanism has a function in influencing the otolith organs in postural deviations of the head and perhaps the semicircular canals in postural movements it is not clear what this function is and does not appear to be an essential one In modern man easy and early vomiting is an unnecessary safety device

The LCAs are easily disturbed and much evidence for this statement would most certainly be forthcoming with further study It is useful to make some acceptable generalizations that would appear to be in support. The LCAs are in the temporal lobe This lobe constitutes the most recently developed part of the brain Penfield *(1960)* calls it the integrative cortex and it finds its *highest* development in homo sapiens It is well known that *new structures become* more readily *disturbed than old ones* This is also a reason why the disturbances *described here* should occur in the *cortex and not elsewhere* The single commonest *side effect* of all drugs is dizziness *The symptom common to all acute* poisoning is nausea and vomiting (Brainerd et al *1965) and this is not necessarily* due to *gastric irritation* e g. in excessive alcohol ingestion *(Laurence 1967) Dizziness* is not mentioned in the text because it would appear an unnecessary observation in the recognition of such a serious condition as *acute* poisoning; but dizziness and delayed taste perception will undoubtedly be found even when the patient has recovered from the acute symptoms and prostration. Any *writer of* detective fiction describing the condition of his hero who rises from an unconscious state after receiving a blow on his head will say that the subject is dizzy and sick, that he is unsteady when he tries to rise up that there is a buzzing *in the* head and a pounding pain Even after a mild head injury where the subject only be

ing The pulse is slow and the blood pressure low Colman (1971) says that this is a vagal effect It will be seen that the symptoms and signs are both parasympathetic and sympathetic *It is now clear how severe* vertigo through a vestibulogenic effect and feed back through the LBs leading to a circuit generating hyperactivity causes spreading excitation from the LCAs to the area of autonomic representation thus giving these features The conception of Behrman & Wyke explains how in severe vertigo both reticular areas become activated thus leading to increased excitation in both LCAs which may not be equal If the LB mechanism is very hyperactive spontaneous nystagmus can also occur (cf nystagmus on LB ablation) This excessive cortical activity leads in the rare predisposed subject to a seizure (Behrman & Wyke) and also in rare instances to unconsciousness alone (Golding Wood 1960) This also explains why PN has been found in Menière s disease why directional preponderance or sensitivity has been found in the caloric tests and why the *nystagmus can be unpredictable and found* to change direction (Colman 1971) and also why the sensation of turning or of falling is unpredictable and can be to either side (Golding-Wood 1960) An explanation for these features has been difficult hitherto Only the feature of excessive salivation has not been explained here Penfield (1954) says the cortical area for salivation is at the bottom of the motor area nearby Arulpragasam (1967) found PN in the syndrome of vertigo and salivary gland enlargement and in recurrent parotitis These conditions he stated were due to excessive secretory activity engendered by an epileptiform process It is now known that in these conditions there is a *taste delay* thus placing the disturbance in the cortical area under consideration here It appears that hyperventilation can also be explained but will not be undertaken What is less well documented is the fact that in moderately severe vertigo a *rise of blood pressure will be found* Any family physician will confirm that this is a common occurrence. His explanation for this will differ from what is advanced here *It is clear that spreading excitation in the LCAs in moderately severe vertigo will bring the temporary elevation of blood pressure that* has been so commonly observed It is the vertigo that brings about such elevation and not the elevated blood pressure *the vertigo* as it is now believed to be the explanation Van Buren (1958) studying temporal lobe epilepsy and the autonomic concomitants of ictal automatism found rise of blood pressure tachycardia lacrimation retching flushing of the face swallowing and other changes relevant here A recorded fall in blood pressure did not occur among his cases but he gives an explanation of why this may not have been recorded He came to the conclusion that there is probably spatial separation of the representation of autonomic function in the temporal cortex A delay in taste perception must occur in the situations discussed here

Wood & Graybiel (1973) say the symptoms of motion sickness vary with the individual although in a given individual the same pattern of signs and symptoms will follow repeatedly They may include any or all of the following drowsiness yawning salivation swallowing hyperventilation headache and flushing followed by pallor of increasing intensity Cold sweat on the forehead underarms hands and around the mouth is frequently observed Increasing nausea may lead to vomiting To this the author adds minor itching of the ears and *fulness of the ears during the nausea* In nausea there is a bitter taste in the mouth and it will not be surprising if taste perception will be found delayed that there is a PN in acceleration deceleration and stoppage of movement is well known How *the disordered vestibular afferents in motion* bring about an excitation of the LCAs and the neuronic circuit described here will

further stimulate the labyrinths and through a vestibulogenic effect bring about spreading excitation from the LCAs is clear It will be noticed that these symptoms and signs strongly resemble those found in the muscle contraction headaches and the state of col lapse of a severe Menière s attack. If as in the headaches the neuronic circuit is broken relief should follow This can be achieved in two ways one is to destroy the labyrinth or the afferents on both sides and that this will bring relief has already been found (e.g. deaf mutes with defective laby rinths react differently when tested Wood & Graybiel 1973) The other way is to ablate the LBs There is some evidence in this study itself that this will prove beneficial Since fresh light on the subject of motion sickness is eagerly being sought particu larly at the present time the following ex perimental evidence can usefully be juxtaposed since it will be found to support the views expressed here Jongkees (1960) citing the experimental work of Fernandez et al says that the lesions of the nodulus cerebelli in the rabbit give PN which disappeared when the labyrinth was destroyed Keel & Neil (1966) record that electrical stimulation of the flocculonodular lobe of the cerebellum brings about evoked potentials in the ecto-sylvian gyri of the cat and the dog and comment on how extensive the vestibular representation in the cortex is (This in itself is evidence for the LCA and its location, since the cerebellum is not known to have connections with sensory areas of the cor tex Its function is to suitably modify cor ticofugal effector effects) These authors also state that the auditory sensory area in these animals is in the ecto-sylvian gyri Hence it follows that the ecto-sylvian gyri in these animals correspond to the LCA and Heschl s gyrus in man Then they say that if the nodulus cerebelli is removed in a dog, the animal cannot thereafter be made to be come motion sick.

It would appear that in all nausea there is a disturbance in the LBs This is stated in order to suggest that the original function of the LBs in phylogeny was to trigger off nausea and vomiting. If this mechanism has a function in influencing the otolith organs in postural deviations of the head and perhaps the semicircular canals in postural move ments it is not clear what this function is and does not appear to be an essential one In modern man easy and early vomiting is an unnecessary safety device

The LCAs are easily disturbed and much evidence for this statement would most cer tainly be forthcoming with further study It is useful to make some acceptable gener alizations that would appear to be in support. The LCAs are in the temporal lobe This lobe constitutes the most recently de veloped part of the brain Penfield (1960) calls it the integrative cortex and it finds its highest development in homo sapiens. It is well known that new structures become more readily disturbed than old ones. This is also a reason why the distur bances described here should occur in the cortex and not elsewhere. The single commonest side effect of all drugs is dizzi ness The symptom common to all acute poisoning is nausea and vomiting (Brainerd et al 1965) and this is not necessarily due to gastric irritation e g in excessive alcohol ingestion (Laurence 1967) Dizziness is not mentioned in the text because it would appear an unnecessary observation in the recognition of such a serious condition as acute poisoning; but dizziness and delayed taste perception will undoubtedly be found even when the patient has recovered from the acute symptoms and prostration Any writer of detective fiction describing the condition of his hero who rises from an unconscious state after receiving a blow on his head will say that the subject is dizzy and sick, that he is unsteady when he tries to rise up that there is a buzzing in the head and a pounding pain Even after a mild head injury where the subject only be-

comes dazed PN and delayed taste perception (of over 20 sec) will be found In the mild cases at any rate these will be found to cease with recovery It is evident what the post-concussional syndrome is The symptoms resemble the muscle contraction headache closely Cabral (1972) says that it is a puzzling condition It would appear that the puzzle has been unravelled The youngest case in this series was evidently in retrospect a case of post-concussional syndrome. When corroboration that the post concussional syndrome is what it is suggested here to be is established it would constitute powerful support for the views advanced here and elevate these views from merely being an acceptable hypothesis into something else again It is well known that sustained muscle contraction is the main cause of the headache in the post-concussional syndrome and dizziness defective memory and anxiety are also listed among the symptoms (Mayer-Gross et al 1960) It is for this reason (that the LCAs are easily disturbed) that the functional headaches are so common and both vascular and muscle contraction headaches are due to a derangement of a mechanism which includes the LCA It will be agreed that this is a logical development

Vascular headaches

While PN and delayed taste will be found to occur during the headache they may not be present when the patient presents for treatment From what has arisen here the ear to be operated on would be the one on the headache side Since the headache is usually unilateral only one ear need be operated on usually It is suggested that the severe status *migraine and cluster headache* be first considered for treatment They will present with a headache and the relief afforded therefore dramatic Since it appears to have been established that in the vascular headaches the immediate cause of the head ache is a contraction and dilatation of the intra and extra cranial blood vessels it need only be postulated that in the people predisposed to these headaches there is an intermittent spread of excitation from the LCA to an area of autonomic representation nearby on the temporal cortex which controls the calibre of these blood vessels.

It is evident that in this work in 47 cases *direction-changing PN and in 53 cases* direction-fixed PN have been abolished Hence an acceptable deduction can be made about their mechanism of production Since Aschan (1960) inclines to the view that with alcohol ingestion the PN is a peripheral effect *it is likely to be found that alcohol* PN is also produced by this mechanism

It would appear that the validity of the concept that each temporal lobe is connected to the opposite labyrinth by a LB of the CT nerve is established there is a labyrinthine branch

Summary

The conception of headaches with positional nystagmus (PN) *has been used here to de*scribe the common troublesome and fre*quently recurring* and spontaneously occurring muscle-contraction headaches Two new signs are described with regard to them PN and delayed taste perception on the anterior two-thirds of the tongue to the *application of* moist salt crystals It was *shown that the PN can be made to dis*appear and that taste perception could be expected to return to normal when these patients were treated in the manner de*scribed On the basis of a certain as yet* unaccepted *neuro-otological* conception and by using a minor otological surgical

interference it was possible to cure 100 consecutive cases of these headaches and thus come to a conclusion as to their mechanism of production. Anticipating the likely importance and also because their mechanisms of production are likely to be found to be akin to the mechanism discussed here acceptable hypotheses are set out here about Motion Sickness and the Vascular Headaches It will be recognised when what has been said here is substantiated by other investigators that this will represent the cure for all known recurrent troublesome functional headaches both muscle-contraction and vascular This would have become possible as a result of the author s conception that there is a connection between one temporal lobe and the opposite labyrinth through the labyrinthine branch of the chorda tympani nerve The results here described alone would constitute overwhelming evidence that there must be and there is such a labyrinthine branch In this early study made in 1966 the chorda tympani was avulsed at a certain point in its course in the ear in order to break the labyrinthine branch Even in this series 3 patients were cured when the author had satisfied himself at operation, that the branch had snapped and the chordas themselves were therefore spared It is useful to state also that this procedure has been subsequently used with ablation of the labyrinthine branch or branches only with the same satisfactory results The procedure for such ablation is described here, thus obviating the necessity of making another report on the same subject.

CONTENTS

Introduction

Over the past several years many children with speech and language disorders have been referred to the Pedoaudiological Clinic at the St. Gallen Kantonsspital. A number of these children have language problems which may be attributed to profound hearing losses. Obviously a child who can not hear the sounds of speech will not learn to talk. Other defects of an organic nature, such as cerebral palsy, may interfere with the production of speech sounds. These children may learn to understand speech sounds but be unable to perform the highly complex motor patterns to produce them. Some children are mentally retarded to such a degree that they have not reached the required psychomotor level of development necessary for language acquisition.

Thus there are many causes for speech problems in children. However, there are some cases whose speech and language difficulty can not be attributed to peripheral sensory disorders, structural deformities, motoric disfunction or mental retardation. Such clinical cases are the focus of this study. Therapists working with this group have the impression that these children differ from normal children not just in their failure to develop adequate speech and language skills, but even more in non-verbal behavior. Then too, clinical observation gives the impression that the clinical group may not be homogeneous for some appear to have a serious lag in symbolic performance while others do not.

As a consequence of these observations a preliminary research effort was organized to investigate the clinical group. It was hoped that research would lead to more exact studies in the future. This article reports on the results of this preliminary research.

Problem

Specifically, two questions were posed. First, what characteristics differentiate these handicapped children from normal children of the same age? Secondly, are the handicapped homogeneous or composed of subgroups or so individualistic that no classificatory principle can be found?

Methods and Procedures

The general research plan followed in this study consisted of two steps. First, a normal group of children was compared to a clinical group. Secondly, comparisons were made within the clinical group. Both groups were observed on a series of tasks thought on the basis of clinical observations to be critical in distinguishing between and [illegible]. Since few standardized tests [illegible] to language-disturbed children [illegible]

[illegible]

(SON) to evaluate their ability to structure and reproduce visual patterns Finally two visual tests paralleling the acoustic dimension analysis and sequence discrimination were administered In the first of these a same or different judgment was required in the discrimination of the color and size of two rectangles A similar judgment was required in a test of the ability to discriminate visual sequences composed of two colors and two sizes of rectangles in various combinations (Affolter et al 1974)

Gene al behavi r

The evaluation of general behavior was based on testing direct observation and with the clinical group on video tape recordings of the child Attention span the child's ability to focus on a timulus for a length of time is the first general behavior presented here At this point observations were not concerned with the nature of the task or the specific nature of the stimulus Children with short attention spans start many activities but com plet few Such children may appear hyper active s they change one toy for another or run from game to game Observations such as the length of time a child pursued a partic ular task the number of different toys played with and the number of tasks completed were used to evaluate attention span

Another aspect of general behavior anticipation, requires the child to integrate a series of successive activities Evaluation of anticipation was based mainly on clinical observation Howe er with the younger children and with the se erely handicapped children a task from the Borel Maisonny (1963) test was adapted The ta k referred to here was the beads-tube task In thi case it was used as a means of e king responses f r observational purposes In the bead tube problem the examiner pa ses a string of bead through a wooden tube A normal child will watch for the beads to emerge from the bottom of the tube when the examiner insert the beads at the top Often the child will put out his hand to catch the beads Children with anticipation problems seem surprised when the beads reappear Play audiometry also allows observation of anticipation In play audiometry the child is expected to select a part of a game hold it to the loudspeaker remove the part at the sound of a tone and then proceed with the game Another aspect of general behavior is hand-eye-coordination and body-eye-coordination This requires hand movements to be guided by visual monitoring as for example inserting a key into a lock However it may be used in a broad sense to refer to visual guidance of body movement as when picking up objects from the floor This ability was observed using play activities of varying difficulty such as simple block constructions as opposed to intricate close-fitting puzzles Shifting behavior was evaluated also Shifting requires that one change his point of view or his ongoing activity For example a child must shift when requested to change from sorting on the basis of form to sort on the basis of color It was found that portions of non verbal tests could be adapted to permit observation of the ability to shift

Elaborative functions

Elaborative functions refer to performance which is characteristic of intelligent behavior in the sense used by Piaget (1947) In his genet ic theory Piaget considers intelligence to develop in a number of stages The first stage is the sensory-motor the second is the intuitive then the pre-operative next the concrete and then the formal intelligence stage The formal level is characteristic of children older than 1 years so this research includes only the earlier levels since the oldest children studied were only ten Inasmuch as the clinical group of children was seriously delayed in language development the intuitive and pre operative stages were emphasized for these levels are characterized by language acquisition Furthermore since some children in the clinical group appear to lag behind or even lack symbolic function emphasis was also

also to use clinical observation As an aid to observation periodic video tape recordings were made of the children s behavior These tapes were reviewed analyzed and evaluated by a team of trained audiologists speech therapists and psychologists on the clinic s professional staff

Subjects

Thirty subjects were selected for the clinical group from children under longitudinal observation at the Pedoaudiological Clinic This group ranging in age from three to ten years was representative of children whose sensory deficit if existent or mental retardation did not appear to account for their language problem For example this group included some deaf children who appeared to be more language handicapped than other deaf children of the same age and history

Another group of thirty children matched in age to the clinical group made up the normal group of subjects in this study These children were considered normal if they were progressing in a public school or kindergarten program without difficulty or in the case of younger children if they scored in the normal category of a non verbal intelligence test Several of the normal group were siblings of children in the clinical group and were consequently of a similar socio-economic level The remainder of the normal group were children of hospital personnel or their relatives

Between groups comparisons

Tests and observations

Overall four types of information were collected on the two groups of subjects The first type input consisted of evaluations of the child s auditory and visual acuity In addition the child s ability to discriminate auditory and visual dimensions patterns and sequences was tested whenever possible The second type general behavior consisted of observations of the child s behavior in various dimensions such as ability to concentrate to anticipate to exercise caution and other behavioral traits The third type elaborative functions consisted of evaluation of the child s performance on sensory-motor operative and figurative tasks The fourth speech sound production consisted of evaluation of speech sound production and ability to imitate speech sounds The specific tests and observations are presented below

Input audition

All children in both groups were assessed for hearing sensitivity by pure tone audiometry Play audiometry was used with preschool subjects to establish thresholds for the frequencies 250 to 6000 Hz. Whenever the child would not accept headphones free field tests were used to establish binaural thresholds For older subjects standard pure tone audiometry was used to determine thresholds for the frequencies 125 to 8000 Hz (criterion for normal hearing was an average air-conduction threshold of less than 20 dB (re HL ISO) at the frequencies 500–4000 Hz)

Speech audiometry was used to obtain speech discrimination scores on those subjects able to respond (criterion for normal speech discrimination was an intelligibility score of 100 percent at 63 dB re SPL) A test of acoustic dimensional analysis followed which required the children to make a same or different response to two different frequencies and two different intensity levels A similar judgment was required in a test of discrimination of acoustic sequences combining two frequencies and two intensity levels in various patterns

Input vision

Ophthalmologic referrals were made for all subjects suspected of having visual difficulties Older children (ages 5 to 10 years) were given the mosaic subtest of the Snijders Oomen (1964) non verbal intelligence test

Hz, a measurement of time can be made so that the rate of speaking can be calculated

Plug-in component the kay model 6016 C scale magnifier permits the expansion of selected portions of the voice spectrum so that individual harmonics can be identified From this the change in vocal frequency over time can be seen and the intonation contour of the utterance observed The older children were asked to say Ich gehe über die Strasse and Sprechen Sie Deutsch?" The question was replaced by "Was machst du for the younger children All of the normal group and part of the clinical group were recorded live voice The remainder were recorded on audio-tape from which selected cases were used for spectrographic analysis The audiotapes were used also for phonemic analysis of the child s speech

Within groups comparisons

The previou ection presented the methods and procedures by which it was attempted to determine what characteristics of the clinical group differentiated them from normal children of the same age This section describes the methods and procedures used to determine if the clinical group was homogeneous or composed of subgroups or so individualistic that no classificatory subgroups could be formed.

Clinical observations of the clinical group had gi en the impression that some of this group lagged or perhaps lacked symbolic function So the clinical group was divided on thi basis forming two subgroups The first subgroup A was composed of 18 children who appeared clinically to have symbolic function The second subgroup B consisted of [illegible] children who appeared clinically to be seriously retarded in or lacking symbolic function

Again the children performances were studied This time the basis upon which tasks were selected stemmed mainly from clinical observation and Piaget s genetic theory More specific subtasks were formed to permit more detailed observation of the performances of the two subgroups. For example genetic theory and clinical observations suggest that aspects of general behavior and elaborative function may discriminate within the clinical group so these performances were studied in a more specific fashion

Input

With regard to input functions the observations enumerated in the previous section on the between groups comparison were used This information was considered to be sufficiently detailed for within-group discrimination if in fact discrimination can be made on this dimension However clinical impressions suggest that such discrimination will not be obtained using modality specific information

General Behavior

General behavior performances observed for the within-group comparison included attention span, anticipation body-eye (including hand-eye) coordination and shifting behavior The first, attention span was defined previously as the ability to focus on a stimulus over time leaving the stimulus unspecified Clinical impression suggests that it might be meaningful to investigate performances requiring focus on tactile kinesthetic stimuli such as assembling jig-saw puzzles or other performances in which monitoring can be tactile–kinesthetic rather than tactile–kinesthetic–visual Another clinical impression concerned attention as seen in play audiometry In this situation the child must integrate a series of activities This integration requires a critical length of an "attention type often called waiting behavior For example can the child hold a toy against the loudspeaker for a long enough time to allow the audiometrist to vary the presentation interval of the tone In other words can the child "wait for the tone to come

Anticipation was divided into several as-

given to the sensory motor stage considered as a prerequisite for symbolic function

Information concerning the sensory motor and intuitive level was collected by observing direct imitation Direct imitation the ability to reproduce an activity at the moment or immediately after the original is produced marks the end of the sensory motor period (Piaget 1945) Therefore disturbances of this stage should be reflected in problems of direct imitation Deferred imitation the ability to reproduce an observed activity after a period of time has elapsed since the production of the original activity marks the beginning of the next stage If a child fails to develop deferred imitation it can be argued that he has not reached the intuitive stage Consequently observations of imitative behavior were considered significant in this research From the end of the sensory motor stage on there is an increasing differentiation of figurative processes and operative processes One of the most marked of the figurative processes is language which the child discovers by the middle of the second year Drawing performances can be considered an important expression of figurative processes in the older child and may be studied by observations of spontaneous drawings (Piaget *et al* 1948) The criterion for judging appropriateness was the age of the child beginning to draw If the child had no graphic expressions by the age of 5 years his performance was considered inappropriate Therefore one can study figurative processes in the child by observing his language and drawings Operative processes may be evaluated by scores the older child obtains in the SON sorting subtest For younger children this was accomplished by using the puzzles of the Borel Maisonny battery

Superficial observations of the severely handicapped children of the clinical group often give the impression that they are mentally retarded To investigate if the clinical group differs from the normal group because of mental retardation two kinds of information were collected First the linearity of the SON subtests was considered In intelligence testing it is assumed that a child scoring at the eight year level on one subtest will score at the eight year level on another That is to say the normal child s scores on various parts of the overall test will be consistent and present a linear profile without discrepancies The mentally retarded will show the same linear profile except that the level will be two or three years lower than the chronological age would indicate To investigate the linearity of such a profile in the groups three subtests of the SON-battery were used the mosaic memory and sorting subtests If the difference between any two of these tests was more than one and one half years the profile was considered non-linear Another way of investigating the problem of retardation raised above is to collect information about the linearity between operative and figurative processes and the relationship between direct and deferred imitation According to Piaget direct imitation marks the end of the sensory motor stage and deferred imitation marks the next higher level the intuitive stage (Piaget 1945) Therefore one would not expect a child to perform better in deferred imitation than in direct imitation It can be expected that a mentally retarded child will present a linear profile of retardation in operative and figurative processes and will also show better performances in direct imitation and poorer in deferred imitation

Speech sound production

Speech sound production was studied by means of a Kay Electric model 6061 B spectrum analyzer The Kay machine converts spoken sounds into a visual graph (a spectrogram) of frequencies and intensities as a function of time In general frequencies above 3 000 Hz are associated with consonants while vowels appear as bands of energy (formants) below 3 000 Hz. From the spectrogram which covers a range from 100 to 8 000

Hz, a measurement of time can be made so that the rate of speaking can be cal culated

Plug-in component the Kay model 6016 C scale magnifier permits the expansion of selected portions of the voice spectrum so that individual harmonics can be identified From this the change in vocal frequency over time can be seen and the intonation contour of the utterance observed The older children were asked to say Ich *gehe über die Strasse* and Sprechen Sie Deutsch The question was replaced by 'Was *machst du* for the younger children All of the normal group and part of the clinical group were recorded live voice The remainder were recorded on audio-tape from which selected cases were used for spectrographic analysis. The audio-tapes were used also for phonemic analysis of the child s speech

Speech sound production

Speech sound production was studied by *means of a Kay Electric model 6061* B spectrum analyzer The Kay machine converts spoken sound into a visual graph (a spectrogram) of frequencies and intensities as a func*tion of time In general frequencies above* 3 000 Hz are associated with consonants while vowels appear as bands of energy (formants) below 3000 Hz From the spectrogram *which covers a range from 100 to 8000*

Hz, a measurement of time can be made so that the rate of speaking can be calculated.

Plug-in component the Kay model 6016 C scale magnifier permits the expansion of selected portions of the voice spectrum so that individual harmonics can be identified. From this the change in vocal frequency over time can be seen and the intonation contour of the utterance observed. The older children were asked to say "Ich gehe über die Strasse" and "Sprechen Sie Deutsch?" The question was replaced by "Was machst du?" for the younger children. All of the normal group and part of the clinical group were recorded "live voice". The remainder were recorded on audio-tape from which selected cases were used for spectrographic analysis. The audio-tapes were used also for phonemic analysis of the child's speech.

Within groups comparisons

The previous section presented the methods and procedures by which it was attempted to determine what characteristics of the clinical group differentiated them from normal children of the same age. This section describes the methods and procedures used to determine if the clinical group was homogeneous or composed of subgroups or so individualistic that no classificatory subgroups could be formed.

Clinical observations of the clinical group had given the impression that some of this group lagged, or perhaps lacked, symbolic function. So the clinical group was divided on this basis forming two subgroups. The first, subgroup A, was composed of 18 children who appeared clinically to have symbolic function. The second, subgroup B, consisted of 12 children who appeared clinically to be seriously retarded in, or lacking, symbolic function.

Again the children's performances were studied. This time the basis upon which tasks were selected stemmed mainly from clinical observation and Piaget's genetic theory. More specific subtasks were formed to permit more detailed observation of the performances of the two subgroups. For example, genetic theory and clinical observations suggest that aspects of general behavior and elaborative function may discriminate within the clinical group so these performances were studied in a more specific fashion.

Input

With regard to input functions, the observations enumerated in the previous section on the between groups comparison were used. This information was considered to be sufficiently detailed for within-group discrimination if, in fact, discrimination can be made on this dimension. However, clinical impressions suggest that such discrimination will not be obtained using modality specific information.

General Behavior

General behavior performances observed for the within-group comparison included attention span, anticipation, body-eye (including hand-eye) coordination and shifting behavior. The first, attention span, was defined previously as the ability to focus on a stimulus over time, leaving the stimulus unspecified. Clinical impression suggests that it might be meaningful to investigate performances requiring focus on tactile-kinesthetic stimuli, such as assembling jig-saw puzzles or other performances in which monitoring can be tactile-kinesthetic rather than tactile-kinesthetic-visual. Another clinical impression concerned attention as seen in play audiometry. In this situation the child must integrate a series of activities. This integration requires a critical length of an "attention" type often called "waiting" behavior. For example, can the child hold a toy against the loudspeaker for a long enough time to allow the audiometrist to vary the presentation interval of the tone? In other words can the child "wait" for the tone to come.

Anticipation was divided into several as

pects Clinically it is thought that in order to move adequately in a complex situation the child must integrate and anticipate a series of successive events For example consider a task such as putting an assembled wooden jig saw puzzle back into the game closet Here the child must pick up the completed puzzle carefully so as not to spill it hold it even while walking to the closet avoid bumping into objects which would jar the puzzle loose open the closet without spilling it and slide the puzzle into place without knocking it apart Another form of anticipation is seen on the Borel Maisonny beads-tube task Here it is expected that the child anticipates the emergence of the beads after they have been inserted and will be seen to avert his gaze to the bottom of the tube If the child catches the beads in his hand the performance can be considered tactile–kinesthetic–visual Anticipation is thought to be involved in play audiometry Here the task is a tactile–kinesthetic–auditory activity In play audiometry the child must pick up a puzzle piece or toy place it on the loudspeaker hold it there putting it down only after he hears the tone

Precautionary moves such as those taken when the child sees a large strange dog or when crossing the street presuppose previous tactile–kinesthetic experience The expectancy of danger is monitored visually and reacted to in a tactile–kinesthetic manner i e by running away Consequently observation of whether the child exercises reasonable caution is significant Initial stupor is defined as a brief interruption of ongoing activity when an unknown person enters a room or a brief hesitation when the child confronts a new situation As with precautionary moves initial stupor indicates that the child has learned from past experience He inspects newcomers visually for the presence of any threat that would call for tactile–kinesthetic reaction Children with problems of initial stupor may not interrupt their activities or they may overreact and flee from the situation Eye contact may be similarly interpreted

Body–eye (or hand–eye) coordination was also studied The child s ability to perform complex motor tasks requiring tactile–kinesthetic coordination such as climbing is considered clinically significant Through vision the child acquires information concerning the object he is climbing his actual movements are monitored tactually–kinesthetically

Shifting behavior was defined as a difficulty in changing a point of view or an ongoing activity More detailed aspects were observed for the within group comparison Observations of stereotyped movements were collected For example some children will rock back and forth spin an object or voice a syllable almost endlessly Another category concerned compulsive behavior Compulsive behavior is an activity with objects which appear to dominate the child For example a child may have to take all of the keys or collect all of the toy cars or line up objects in a certain way before one can work with him

Elaborative performances

In the previous section it was pointed out that aspects of three stages of intelligence (in Piaget s sense) were investigated the sensory motor the intuitive and the preoperative stages To inquire about sensory motor integrity and the beginning of intuitive intelligence imitative behavior was studied Observations of language and drawing performances were thought to give information about figurative processes and sorting performance to give information about operative processes The linearity of scores on some subtests of the SON battery and the discrepancy between the success of direct imitation and deferred imitation were considered to give some basis for discussing the problem of mental retardation It was considered that such data would be sufficient to differentiate the clinical group from the normal group However clinical observation leads to the assumption that for

comparisons of elaborative processes within the clinical group more detailed information would be needed. Therefore each stage of intelligence was divided into more aspects by referring again to Piaget's genetic findings.

Instead of taking imitative behavior as the only representative of the sensory-motor stage more elementary processes were studied. Perceptual intermodality performances were investigated by observing localization responses. Music and animal calls were presented through two loud speakers to the right and to the left of the child. If when a child heard the sound he turned his head in direction of the sound source to look at it the response was considered appropriate.

Piaget considers that modality specific performance develops prior to perceptual intermodality performances. For example a child will explore an object separately by tactile or visual means or a sound by auditory means before he can relate the different modalities. Consequently listening behavior and visual matching of simple figures or forms were considered to yield relevant information about modality specific performance of vision and audition. Figurative processes include several aspects according to Piaget. Language and drawing performances were studied. This time children of subgroup A and subgroup B older than 5 years were compared on the basis of whether or not they had acquired some graphic expressions. Besides language and drawing as two expressions of semiotic function, symbolic play and the use of pictures or picture recognition also depend upon the presence of semiotic function. Therefore it was thought that observations of picture recognition and symbolic play would give important insight into the development of semiotic processes in the clinical cases. Symbolic play behavior in the younger children was studied by presenting them the "bowl" of the BM-battery. The bowl includes a number of small objects such as a car, a cup, spoon and plates, a church and a house. The child's play behavior with the toys was observed. Do the objects have some meaning for the child, does he handle them symbolically. For example the car is to drive around, the cup to be put on the plate, the spoon to eat something from the plate. Other clinical observations about the child's symbolic play behavior included reports from parents about the child's play behavior at home. Furthermore the child's speech production was observed for meaning. Does the child attempt to communicate with the few speech sounds he has acquired?

In the previous section operative behavior was studied by observing sorting performance. In the within group comparison attention was focused on the nature of the task material. For example the geometric forms sorting task of the SON was considered to be a visual performance without symbolic meaning involved. On the other hand the child's performance on the jig-saw puzzles was considered as a tactile–kinesthetic task.

Results and Discussion

Between groups comparisons

Input

The first observations collected on the normal and clinical group were concerned with input functions. Basically the focus here was to determine if the auditory and visual mechanisms were functioning within normal limits. The input results, shown in Table I, are presented as the number of subjects in parentheses and as percentages of the group. Thus the dash in the first cell of the columns to the left means that none of the normal children were unable to be tested for pure tone

thresholds Therefore the entry of 30 the total number of the normal group in the second cell indicates that all normal children could be tested In the clinical group seven children or 23% could not be tested They failed to learn the rules for play audiometry (This failure will be analysed in detail in the discussion about differences within the group) Twenty three (76%) of the clinical group could be tested The four columns to the right of Table I present the results for the children who could be tested The first two columns on the right present the results for the normal children tested The second two columns are the results for the clinical children tested The terms appropriate or inappropriate were used to indicate whether the children s responses were within normal limits A response was judged inappropriate by the research team if it fell outside the normal range or if it attracted the research team s attention alerting them to possible problems For the normal group 27 children (90%) gave pure tone thresholds within normal limits Three children (10%) did not meet normal expectancies present

ing conductive hearing losses which were treated medically afterwards. Eight children (35%) of the clinical cases presented normal thresholds. 15 children (65%) did score inappropriately. Eleven had a severe hearing loss belonging to the group of deaf children included in the research. Four had a hearing loss of a conductive nature and received medical treatment.

Fifty percent of the normal children had normal visual acuity as evaluated by traditional screening procedures in their schools. Reports of the parents and observations in the clinic pointed out that the other 50% did not appear to have difficulty in visual acuity. Three of the clinical cases had ophthalmological examinations. Two of them wear glasses; one child is still under ophthalmological observation. Twenty-seven (89%) of the clinical cases had had no medical eye examinations. However, their parents and therapists reported no visual particularities.

Seventy-seven percent of the normal group could be tested on analysis of acoustic dimensions, 71% on visual analysis. The children who failed to take these tests were unable to give appropriate responses because they were too young, less than four years of age. Scores were within normal limits for 96% of children tested on auditory and visual analysis. One child failed to perform adequately on visual analysis, another child on auditory analysis.

Only 70% of the clinical group could be tested on auditory analysis, 30% on visual analysis. The number in the "not tested" column were clinical children who were either too young or unable to respond adequately because of the severeness of their handicap. About one-third of those tested scored inappropriate on both auditory and visual analysis. Their failures appear to be due more to the difficulty of understanding the task than to a specific problem of dimensional analysis.

Speech discrimination could be evaluated in the 22 children of the normal group who were older than 6 years of age. Five children (23%) gave inappropriate responses. They needed more amplification than the other children to achieve a score of 100 percent correct responses or they failed to reach a 100% level. However, for pure tone thresholds these five children had scored appropriately.

Only 6 children of the clinical group were able to take the test for speech discrimination. The other children were either too young or too severely hearing-impaired or lacked the necessary speech skills to take the test. Of the tested children, only one child scored inappropriately, thus giving a higher percentage of success in the clinical group than in the normal group. Different results are found in the visual test, the SON mosaic test. Here more children in both groups could be tested than in the speech discrimination test since the mosaic test is applicable to a younger age range than the speech-discrimination test and is of a non-verbal type. On the visual test the percentage of failure in the normal group is about the same as that found for speech discrimination. Six children (24%) failed the visual problems, while 5 children (23%) failed the auditory problems. Of the clinical cases 67% responded inappropriately. However, since more clinical children were exposed to this non-verbal task than to the speech discrimination task, it is to be expected that more children would fail. Inappropriate as used here does not mean that these children have visual difficulty but rather that they failed to adapt to the test situation, a finding confirmed by the therapists' judgments.

The results of the sequencing tasks point out that the number of children who could be tested became smaller as the difficulty level increased from task (a) to task (c) for both the normal and clinical groups. This trend in the normal group is about the same for the auditory and the visual tasks. In the clinical group the number of non-tested children is higher for the acoustic series than for the visual series.

thresholds Therefore the entry of 30 the total number of the normal group in the second cell indicates that all normal children could be tested In the clinical group seven children or 23% could not be tested They failed to learn the rules for play audiometry (*This failure will be analysed in detail in the* discussion about differences within the group) Twenty three (76%) of the clinical *group could be tested The four columns to* the right of Table I present the results for the children who could be tested The first two columns *on the right present the results* for the normal children tested The second two columns are the results for the clinical children tested The terms appropriate or inappropriate were used to indicate whether the children s responses were within normal limits A response was judged inappropriate by the research team if it fell outside the normal range or if it attracted the research team s attention alerting them to possible problems For the normal group 27 children (90%) gave pure tone thresholds within normal limits Three children (10%) did not meet normal expectancies present

span caused by even slight increases in complexity of a problem of a room of a situation or of the child s physical condition or even the therapist s attention appear to differentiate the clinical children from the normal children.

Anticipation was judged inappropriate in all children of the clinical group thus differentiating them from the normal children Parents report that these children have difficulty in situations where it is necessary for them to wait Observations in therapy offer strong corroboration of such reports These children have difficulty in waiting at the work table until the therapist brings new work material They stand up and move around without focusing on a specific task These children want to leave immediately at the end of a therapy session. If such a child is told about a future event or activity he expects it to happen immediately Children of the clinical group who were tested on the *Borel-Maisonny* scale demonstrated difficulty in *anticipating the* emergence of the beads from the tube They looked at the upper end where the beads were inserted rather than anticipating them at the lower end When the beads appeared at the bottom the children seemed to be surprised. Children from the clinical group *did not reach for* the beads at the lower end of the tube The previous finding that play audiometry was unsuccessful with 23% of the clinical group appears to be related to anticipation problems For example in play audiometry the child must select a puzzle part, hold it against the loudspeaker wait for the tone, remove the puzzle piece fit it into the puzzle and take another piece to continue the game The clinical children seemed to forget what came next in this series of activities

Similar to the attention span are the observations about changes in body–eye or hand–eye coordination In a similar vein, there is never complete lack of hand–eye coordination in the clinical group In the clinical group coordination was less stable than in the normal group when the level of difficulty of a task was increased For example in assembling a jig-saw puzzle which he has already mastered the clinical subject will exhibit appropriate hand–eye coordination However when the difficulty is increased by telling the child to hurry or by giving him a more complicated puzzle, or by introducing irrelevant stimuli his coordination breaks down. He can no longer move his hands while monitoring them visually His movements become uncoordinated or he gives the impression of working like a blind child

The research team the clinicians and parents noticed that all the children of the clinical group had more difficulty in shifting their point of view or in shifting from one activity to another The parents report that when such a child is taken out of his usual round of activities he gets more restless than normal In therapy when the child with shifting difficulties finds out that his therapist has been changed or that his program has been changed he gets very upset. Shifting difficulties are often obvious on problem solving tasks If the child has inserted the wrong piece in a puzzle he has difficulty taking it out just as he has difficulty when a piece should be reversed The SON-subtest of the mosaic problems presents an opportunity to observe shifting problems There a model is presented in a rectangular *position for* the first few tasks then the position changes into an angle-position Children of the clinical group have difficulty adjusting to such a positional change However once adjusted, the child may perform correctly again and proceed with the test. Another test requires the child to shift from color sorting to form sorting, a shift which is difficult for the clinical child to perform

Elaborative performances

The sensory-motor stage of elaborative performances was evaluated by collecting

Table II *General behavior between groups (numbers of subjects and percentages)*

Anticipation	(30) 100%	–	–	(30) 100%
Hand–eye coordination	(30) 100%	–	–	(30) 100%
Shifting	(30) 100%	–	–	(30) 100%

Summarizing the results of the input perfor mances reveals some tendencies First there *is no input task which appears to separate* clearly the normal from the clinical group Most tests give some inappropriate responses *in the normal group* as well as in the clinical group There are a few normal children whose pure tone thresholds cannot be considered within normal limits Not all normal children have a speech discrimination score of 100% correct Some fail in sequencing tasks of *auditory or visual nature In both the normal* and the clinical groups more children can not be tested or give inappropriate responses when the performances being tested are more complex

However the incidence of children who can not be tested and of children who give in appropriate responses is higher in the clinical group than in the normal group

A similar finding is observed as the tasks in crease in complexity for again the number of children not tested or giving inappropriate responses is greater for the clinical group

A second tendency is also of interest The data for the two groups reveal that an appro priate response on a peripheral task such as pure tone thresholds *does not predict* an appropriate response for a more complex task There are children who have normal pure tone thresholds who do not score appropriately on speech discrimination Then too there are children who score normally on a dimensional analysis but fail sequencing tasks of the same modality

General behavior

General behavior was evaluated exclusively by observation since no standardized tests could be applied However it was surprising to notice the consistency of the reports of psycho logists audiologists therapists and parents when information was compared Table II pre sents the results of these observational evaluation scores All children were judged Therefore there are no tested or non-tested entries in Table II Every child was evaluated for appropriateness in attention span anticipatory performance hand-eye co ordination and *shifting behavior If the be* havior of a child was judged to be inappro priate it does not mean that the specific per *formance was totally lacking* For example all children of the clinical group were judged inappropriate in attention span This is not to say that they have no attention span but rather that the length of time during which attention *is focused upon a stimulus was less stable than normal If a task becomes more diffi* cult attention span of these children de creases more rapidly than normal and they may show signs of panic Therefore atten tion span depends upon the amount of *difficulty which a problem presents A child* may perform adequately on a task at his level but if the therapist raises the amount of difficulty his attention span breaks down more rapidly than expected normally Complexity can also be manipulated by increasing the amount of stimuli external to *the task The child may be able to focus* on a task in a quiet corner with just the *relevant material* on the table However he may be unable to focus on the same task when sitting in the middle of a room with more irrelevant stimuli around him In the first situation he appears at ease while in *the latter he will appear to be hyperactive* Such changes of the stability of attention

misunderstanding of the tasks rather than to deficits in problem solving abilities. The non-verbal SON test was standardized on normal hearing children and on deaf children. The pronounced failure of the clinical group for this test may point out that the problems of the clinical group are different from the problems of deaf children. The Borel Maisonny test is a test for young children. All normal children who were tested passed. Their behavior during the testing pointed out that the test did not present problems for them for they solved the tasks easily. However 50% of the clinical cases failed the test. It appears that the test includes items which are difficult for the clinical group tested. However the possibility of mental retardation cannot be ruled out. In order to examine this possibility the linearity of three subtests of the SON battery was examined. If mental retardation were indeed the explanation then the scores on various subtasks would be consistent and lower than the normal group. However inspection of the data on Table III reveals that more than half of the normal children and 62% of the clinical cases had non-linear profiles. The question of mental retardation remained unresolved.

Clinical observations are recorded last on Table III. All children of the clinical group demonstrated either a consistent non-linearity between operative and figurative performances or presented poorer direct and better deferred imitation. Piaget in a lengthy discussion of the development of operative and figurative performances points out that one can expect a child who has reached a particular level of operative performance will have also developed the same level of figurative performance. Thus when a normal child begins to recognize pictures he also begins to name them and at the same time starts to imitate a model which is no longer present. By the time a child begins to sort objects according to certain qualities or to put them in serial order he begins to draw. This appears to be different in the clinical group. There some children are able to classify or to arrange objects in a series but still cannot recognize pictures or draw. Such non-linearity between relatively well developed operative processes and a consistent lag of figurative performance is inappropriate and seems to differentiate part of the clinical group from the normal group. The other part of the clinical group was found to have better performances in deferred imitation than in direct imitation a relationship which is just the reverse of that found in normal children. As an example of deferred imitation parents and therapists often report that such a child will produce words spontaneously that he has heard several days previously. If an adult says that word and asks the child to repeat it, requiring direct imitation the child fails to do so. The observations here point out that this discrepancy indicates a specific difficulty which differentiates some of the clinical group from the normal group.

Speech sound production

Speech sound production was observed by means of a Kay Electric model 6061 B spectrum analyzer with a 6076 scale magnifier plug-in unit. A group of 20 normal children were observed but due to shyness in the laboratory situation only 17 usable sets of spectrographic recordings were obtained. The 30 children of the clinical group were observed. However only 15 of these children could produce speech leaving 15 clinical subjects who were not recorded on the spectrum analyzer. In addition to the spectrographic recordings a phonemic analysis was made of both groups speech sound production. A summary of the results of examination of the speech sound production of the normal and clinical groups of subjects is presented in Table IV.

The first result presented in Table IV *3000 Hz* is an analysis of spectral components at 3000 Hz or above. The presence of high frequency components in this range is *typical*

Standardized scores

information about imitative behavior Since imitation was evaluated by observations and not by tests there are no entries for tested and not tested children As can be seen on Table III all children of the clinical group were judged inappropriate in imitative behavior This result includes not only the imitation of speech in which all children of the clinical group have difficulty but also non verbal activities such as imitation of gestures facial expressions and other activities Difficulties and delay of development of imitation were observed in both direct imitation and in deferred imitation

It was expected that all clinical children would differ in language performances from the normal children since it was for this reason they came to the clinic and were selected as subjects However the same was not anticipated for drawing performance Table III indicates that all normal children were judged appropriate in this respect which means that by the age of five years the normal children had a means of graphic expression This was not the case with the clinical group All of the clinical cases were judged inappropriate This means that the clinical child by the age of five years had not developed any drawing skills

Operative performance was evaluated by means of the SON sorting test or the BM puzzle items SON test scores of the normal children indicate that 17% responded inappropriately However the number of failures was higher in the clinical group where 77% of the tested children did not perform at their age level Upon analysis of the data and discussions with psychologists it became apparent that this high rate of failure in the clinical group was due to

misunderstanding of the tasks rather than to deficits in problem solving abilities The non-verbal SON test was standardized on normal hearing children and on deaf children The pronounced failure of the clinical group for this test may point out that the problems of the clinical group are different from the problems of deaf children The Borel Maisonny test is a test for young children All normal children who were tested passed Their behavior during the testing pointed out that the test did not present problems for them, for they solved the tasks easily However 50% of the clinical cases failed the test. It appears that the test includes items which are difficult for the clinical group tested However the possibility of mental retardation cannot be ruled out In order to examine this possibility the linearity of three subtests of the *SON* battery was examined If mental retardation were indeed the explanation then the scores on various subtasks would be consistent and lower than the normal group However inspection of the data on Table III reveals that more than half of the normal children and 62% of the clinical cases had non-linear profiles The question of mental retardation remained unresolved

Clinical observations are recorded last on Table III All children of the clinical group demonstrated either a consistent non-linearity between operative and figurative performances or presented poorer direct and better deferred imitation Piaget in a lengthy discussion of the development of operative and figurative performances points out that one can expect a child who has reached a particular level of operative performance will have also developed the same level of figurative performance Thus when a normal child begins to recognize pictures he also begins to name them and at the same time starts to imitate a model which is no longer present By the time a child begins to sort objects according to certain qualities or to put them in serial order he begins to draw This appears to be different in the clinical group There some children are able to classify or to arrange objects in a series but still cannot recognize pictures or draw Such non-linearity between relatively well developed operative processes and a consistent lag of figurative performance is inappropriate and seems to differentiate part of the clinical group from the normal group The other part of the clinical group was found to have better performances in deferred imitation than in direct imitation a relationship which is just the reverse of that found in normal children As an example of deferred imitation parents and therapists often report that such a child will produce words spontaneously that he has heard several days previously If an adult says that word and asks the child to repeat it requiring direct imitation the child fails to do so The observations here point out that this discrepancy indicates a specific difficulty which differentiates some of the clinical group from the normal group

Speech sound production

Speech sound production was observed by means of a Kay Electric model 6061 B spectrum analyzer with a 6076 scale magnifier plug-in unit A group of 20 normal children were observed but due to shyness in the laboratory situation only 17 usable sets of spectrographic recordings were obtained. The 30 children of the clinical group were observed However only 15 of these children could produce speech leaving 15 clinical subjects who were not recorded on the spectrum analyzer In addition to the spectrographic recordings a phonemic analysis was made of both groups speech sound production. A summary of the results of examination of the speech sound production of the normal and clinical groups of subjects is presented in Table IV

The first result presented in Table IV 3 000 Hz is an analysis of spectral components at 3 000 Hz or above The presence of high frequency components in this range is typical

Table IV *Summary of results for speech sound production for the normal and clinical groups between groups (numbers of subjects and percentages)*

(3) 15	(17) 85	(15) 50	(15) 50	Consonant clusters	(17) 100		(1) 7	(14) 93

of consonants and may be used as an index of consonant articulation In Table IV it is seen that all of the normal children s speech is marked by the presence of high frequency components This finding may be regarded as confirming the observation that the normal children produced clear consonants The spectrograms of the clinical group on the other hand offered a marked contrast in this respect Here only 33% of the tested children of this group were found to show spectrographic evidence of the high frequency components accompanying consonant production while 67% were deficient in spectral components above 3 000 Hz This finding may be regarded as confirming the clinical observation that consonant articulations of this group are generally less precise and less intelligible

The next spectrographic interpretation concerns the clarity of vowel formants In the normal speech of adult males clear vowels show formants which are distinct and smooth in appearance Reduced contrast of the formants can result from noise in the vocalic segment and is often caused by voice defects It was for this reason that formant clarity was used in this study However the bandwidth (300 Hz) of the Kay analyzing filter is not ideal for higher pitched voices As a result formant clarity is often reduced in the spectrograms of women and children For this reason the observations concerning formant clarity are to be interpreted cautiously In the normal group 65% revealed clear formant structures as opposed to only 13% of the clinical group This observation suggests a higher incidence of voice problems in the clinical group

The third acoustic factor was considered under intonation The magnifying circuit of the Kay equipment was used to make an expanded spectrogram of the lower 2 000 Hz portion of the child s utterance Expanded spectrograms show the individual harmonics of the voice This enables one to determine the intonation contour as the variation in vocal frequency is called Intonation serves as one of the linguistic cues for questions statements and other types of utterances Of the normal group 76% used appropriate intonation contours for the utterances analysed Similar results were obtained for the clinical group Intonation was the speech sound production ability in which the two groups were most alike

The abscissa of a spectrogram is time so that one can measure the duration of the recorded utterance which in turn allows speaking rate to be calculated All of the normal children were found appropriate having an average rate for the two utterances of 3 3 syllables per second and a range from 2 5 to 4 4 syllables

per second. The slower rates were produced by the younger subjects. These values were regarded as normal for this age group and the type of material spoken. Clinically, the impression was formed that rates of 2.0 syllables per second or below were too slow while rates of 4.5 syllables per second or faster were regarded as too fast for the utterances studied. By this standard, 73% of the clinical group was within the normal classification. The average was 2.9, ranging from 1.7 to 5.2 syllables per second.

The utterances of the two groups of subjects were analysed phonemically. Here the major finding occurred on consonant clusters. All of the normal children were able to produce the consonant sequences in the utterances adequately. However, only seven percent of the clinical group could do so. The clinical subjects showed a marked tendency to simplify consonant sequences by omitting one or more sounds. Thus, the speech of this group tended to consist of consonant-vowel sequences.

The picture which emerges from the analyses of speech sound production is that the normal group differs *markedly* from the clinical group in consonant articulation. The latter group is less proficient in this respect and markedly deficient in the production of consonant sequences. There is some evidence that the clinical *group tends to have* nasalization in their vowel productions which would reduce their clarity. Both groups are relatively able to use intonation *meaningfully*.

Within groups comparisons

As pointed out in the introduction, the clinical group, while all language disturbed, included some children who appeared to lag in symbolic performance as well as some who did not. The clinical group was subdivided into two groups on the basis of symbolic behavior. Subgroup A children seemed to have *symbolic function*. For example, they appeared to recognize pictures and played with dolls and teddy bears. On the other hand, the children in subgroup B seemed to lag, or lack, symbolic function, for they either did not look at pictures or were several years late in doing so. Nor did children in subgroup B play with dolls or stuffed animal toys.

These, and other impressions, led to the second problem of concern in this investigation, namely whether the clinical subjects were a homogeneous group, or as clinical impression seemed to indicate, two different subgroups. Then too, it was possible that investigation would indicate that the clinical group was completely heterogeneous. So the two subgroups were studied in detail to determine if there were consistent differences between the two and if there were similarities within each subgroup. This investigation proceeded along the same dimensions as used previously in the between groups analysis, i.e. input, general behavior, elaborative performance and speech sound production.

The results of input performances are summarized in *Table V*. Overall, it can be seen that more of the subgroup B children could not be tested for input performance than children in subgroup A.

Input

With respect to pure-tone thresholds only two subgroup A children could not be tested while five of subgroup B could *not*. In subgroup A, of the 11 inappropriate responses, seven were from profoundly deaf children *and four* from children with conductive hearing losses. The four inappropriate pure-tone *responses in* subgroup B were from children *with medium* or severe losses. Consequently, pure-tone audiometric results are not seen to differentiate the two subgroups. None of the subgroup B children could be tested on acoustic dimensional analysis apparently because *they failed* to learn the responses necessary for this task. Two-thirds of subgroup A could not be tested on dimensional acoustic analysis but this may be attributed to their hearing handicap. Of those who could be tested in subgroup A, four

15	85	50 %	50		100		7	93

of consonants and may be used as an index of consonant articulation In Table IV it is seen that all of the normal children s speech is marked by the presence of high frequency components This finding may be regarded as confirming the observation that the normal children produced clear consonants The spectrograms of the clinical group on the other hand offered a marked contrast in this respect Here only 33% of the tested children of this group were found to show spectrographic evidence of the high frequency components accompanying consonant production while 67% were deficient in spectral components above 3 000 Hz. This finding may be regarded as confirming the clinical observation that consonant articulations of this group are generally less precise and less intelligible

The next spectrographic interpretation concerns the clarity of vowel formants In the normal speech of adult males clear vowels show formants which are distinct and smooth in appearance Reduced contrast of the formants can result from noise in the vocalic segment and is often caused by voice defects It was for this reason that formant clarity was used in this study However the bandwidth (300 Hz) of the Kay analyzing filter is not ideal for higher pitched voices As a result formant clarity is often reduced in the spectrograms of women and children For this reason the observations concerning formant clarity are to be interpreted cautiously In the normal group 65% revealed clear formant structures as opposed to only 13% of the clinical group This observation suggests a higher incidence of voice problems in the clinical group

The third acoustic factor was considered under intonation The magnifying circuit of the Kay equipment was used to make an expanded spectrogram of the lower 2000 Hz portion of the child s utterance Expanded spectrograms show the individual harmonics of the voice This enables one to determine the intonation contour as the variation in vocal frequency is called Intonation serves as one of the linguistic cues for questions statements and other types of utterances Of the normal group 76% used appropriate intonation contours for the utterances analysed Similar results were obtained for the clinical group Intonation was the speech sound production ability in which the two groups were most alike

The abscissa of a spectrogram is time so that one can measure the duration of the recorded utterance which in turn allows speaking rate to be calculated All of the normal children were found appropriate having an average rate for the two utterances of 3 3 syllables per second and a range from 5 to 4 4 syllables

per second. The slower rates were produced by the younger subjects. These values were regarded as normal for this age group and the type of material spoken. Clinically, the impression was formed that rates of 2.0 syllables per second or below were too slow while rates of 4.5 syllables per second or faster were regarded as too fast for the utterances studied. By this standard, 73% of the clinical group was within the normal classification. The average was 4.9, ranging from 1.7 to 5.2 syllables per second.

The utterances of the two groups of subjects were analysed phonemically. Here the major finding occurred on consonant clusters. All of the normal children were able to produce the consonant sequences in the utterances adequately. However, only seven percent of the clinical group could do so. The clinical subjects showed a marked tendency to simplify consonant sequences by omitting one or more sounds. Thus, the speech of this group tended to consist of consonant-vowel sequences.

The picture which emerges from the analyses of speech sound production is that the normal group differs markedly from the clinical group in consonant articulation. The latter group is less proficient in this respect and markedly deficient in the production of consonant sequences. There is some evidence that the clinical group tends to have noise in their vowel productions which would reduce their clarity. Both groups are relatively able to use intonation meaningfully.

Within groups comparisons

As pointed out in the introduction, the clinical group, while all language disturbed, included some children who appeared to lag in symbolic performance as well as some who did not. The clinical group was subdivided into two groups on the basis of symbolic behavior. Subgroup A children seemed to have symbolic function. For example, they appeared to recognize pictures and played with dolls and teddy bears. On the other hand, the children in subgroup B seemed to lag, or lack, symbolic function for they either did not look at pictures or were several years late in doing so. Nor did children in subgroup B play with dolls or stuffed animal toys.

These, and other impressions, led to the second problem of concern in this investigation, namely whether the clinical subjects were a homogeneous group, or as clinical impression seemed to indicate, two different subgroups. Then, too, it was possible that investigation would indicate that the clinical group was completely heterogenous. So the two subgroups were studied in detail to determine if there were consistent differences between the two and if there were similarities within each subgroup. This investigation proceeded along the same dimensions as used previously in the between groups analysis, i.e., input, general behavior, elaborative performance and speech sound production.

The results of input performances are summarized in Table V. Overall it can be seen that more of the subgroup B children could not be tested for input performance than children in subgroup A.

Input

With respect to pure tone thresholds only two subgroup A children could not be tested while five of subgroup B could not. In subgroup A, of the 11 inappropriate responses, seven were from profoundly deaf children and four from children with conductive hearing losses. The four inappropriate pure-tone responses in subgroup B were from children with medium or severe losses. Consequently, pure-tone audiometric results are not seen to differentiate the two subgroups. None of the subgroup B children could be tested on acoustic dimensional analysis apparently because they failed to learn the responses necessary for this task. Two-thirds of subgroup A could not be tested on dimensional acoustic analysis, but this may be attributed to their hearing handicap. Of those who could be tested in subgroup A, four

Clinical observation

were able to respond appropriately Again there is no basis for differentiating the two subgroups Roughly the same results were obtained on speech discrimination tests Tests of acoustic sequences were too difficult for the subgroup B children as well as for most of the A children Generally the results indicate that the two subgroups cannot be differentiated on the basis of auditory input

With respect to visual performance all children were observed on acuity with all of the subgroup A children appearing to be appropriate and only three (25%) of the second subgroup inappropriate Again on dimensional analysis a visual performance the children of subgroup B failed to achieve sufficiently to be tested while half of the children of subgroup A could be tested Of those tested in subgroup A 67% responded appropriately On the visual mosaic task most of the A children could be tested and most of B could not be tested Only 38% of subgroup A and none of subgroup B performed appropriately on this task The visual sequences were too difficult for the children of subgroup B Some of subgroup A children could be tested with fewer children responding appropriately as the

level of difficulty increased In general it must be said that the visual input results like those for audition do not differentiate the two subgroups

General behavior

All children of the clinical group were judged to have an unstable attention span as reported in the between group results However in controlled situations two observations can be made when the complexity of the situation increases such as having a visitor or when making videotapes the attention span of subgroup A is highly affected Both groups are affected by increased difficulties as when a problem increases above their performance level However group A children demonstrate similar fluctuations of attention span if the material is visual or tactile–kinesthetic or both Children of group B are different. Their attention span is by far the best, even stable, with tactile–kinesthetic materials such as jig saw puzzles. For example a subgroup B child can solve jig-saw puzzles. If a piece falls the child can search for it, pick it up and continue the puzzle. Such a performance cannot be observed in children in subgroup A The subgroup A child who picks up a piece will have forgotten where he was with the solution of the problem

The observations of attention span are divided into three parts and may be seen in Table VI The part two a includes observations on a puzzle of the Borel Maisonny Since the Borel Maisonny is designed for younger children it was used with only 7 of subgroup A and 4 of subgroup B Thus older children are listed as not tested in Table VI Only one child of subgroup A performed inappropriately while the other six performed well The overall test scores on the BM demonstrate that the test was very easy As pointed out earlier inappropriateness of attention span does not mean that the child has no attention span. The child can focus if a problem is at his performance level and if the test situation is not distracting. This was the case for the puzzles of the BM battery What is surprising however is that all children of subgroup B gave appropriate responses This is the only item where children of this group were 100% correct on a standardized test. The inference can be made that this material is easy for the group B child.

Observations using non-standardized tactile kinesthetic material with more complex problems show that the difference between the two subgroups is pronounced As can be seen in 2b of Table VI none of the children in subgroup A performed appropriately while all of subgroup B were successful with tactile–kinesthetic problems

Fluctuations in attention span could also be observed during audiometric testing. A lengthy attention span is required to integrate the series of activities required for play audiometry Group A children gave the impression that they are testable appearing to understand that a tactile–kinesthetic response was required when the tone sounded Inspite of this they failed for their attention span seemed to be too short. For example they would hold a toy on the loudspeaker but not wait for the tone putting it down before the stimuli came The children of subgroup B behaved differently They would hold a toy on the loudspeaker for an extended period When the tone was presented the children appeared to hear it, but they were unable to learn that they had to respond by putting the toy down In short children of subgroup A gave the impression that they cannot wait for the tone while children of subgroup B were able to wait but unable to learn that an auditory signal was to trigger a motor response Of the 7 children of group B who could be tested 71% had appropriate waiting behavior Two were marked inappropriate They were the most severely damaged of the tested children It appears then that subgroup B children have other difficulties than subgroup A children

Anticipation performance appeared to differentiate between the clinical and the normal

Clinical observation

were able to respond appropriately. Again there is no basis for differentiating the two subgroups. Roughly the same results were obtained on speech discrimination tests. Tests of acoustic sequences were too difficult for the subgroup B children as well as for most of the A children. Generally the results indicate that the two subgroups cannot be differentiated on the basis of auditory input.

With respect to visual performance all children were observed on acuity with all of the subgroup A children appearing to be appropriate and only three (25%) of the second subgroup inappropriate. Again on dimensional analysis a visual performance the children of subgroup B failed to achieve sufficiently to be tested while half of the children of subgroup A could be tested. Of those tested in subgroup A 67% responded appropriately. On the visual mosaic task most of the A children could be tested and most of B could not be tested. Only 38% of subgroup A and none of subgroup B performed appropriately on this task. The visual sequences were too difficult for the children of subgroup B. Some of subgroup A children could be tested with fewer children responding appropriately as the

group Clinical observations and parental reports indicated that group A children moved inadequately as soon as a situation became complex For example when they had a complicated jig-saw puzzle and tried to return to a cupboard their movements became inadequate They would stumble and spill the game on the floor When picking up a toy from under the table these children bump their heads Children of subgroup B were not observed to have such difficulties

The next entry in Table VI evaluates the integration of a visual series It was pointed out earlier that children of the clinical group were deviant in anticipatory behavior when tested with the beads-tube task of the BM battery It could be observed however that children of subgroup B can learn visual anticipation in this situation When the children watched the beads being inserted into the tube and appearing again at the lower end they would learn to displace their gaze from the upper to the lower end of the tube thus demonstrating visual anticipation of a visually *perceived* event Howe er they *did* not reach out in anticipation of the beads falling and being picked up Group A children demonstrated difficulty for either anticipation the *visual* or the tactile–kinesthetic type

The next item refers to the play audiometric task. This time the reference is not to waiting behavior but rather to the learning of a tactile–kinesthetic response to an acoustic stimulus to put a toy down when a tone was presented The seven children of group B who could be tested learned the task only after many trials Children of group A did not have this difficulty Their failure of the audiometric task wa due to a difficulty in attention span as discussed previously and not due to the absence of a tactile-kinesthetic response to an acoustic stimulus

Another set of observations also concerns tactile-kinesthetic components but instead of being coupled with an auditory component as in audiometry coupled with a visual component The last set o[illegible] n under anticipation in Table VI is concerned with tactile–kinesthetic–visual integration Parents of children in group A often report that they seem to be over-cautious in simple situations like jumping off a wall or in going with somebody they do not know They lose control in complex situations such as crossing a street When there is only one car they can wait But if there is much traffic they appear to lose their heads and panic

Children of group B behave differently They often run away from home Their mothers have to watch the children continually for they climb walls fences and window sills without realizing the risks they take

Group A children present initial stupor They hesitate when they are in a new situation or when they meet somebody new Not so the group B children They don t seem to notice changes They do not scan a new situation and then adapt to it They either do not notice change or they begin to show panic reactions Eye contact breaks down more rapidly in the children of group B than group A One of the most impressive observations is that these children do not look at you as would another child Group A children however do not differ in eye contact from normal children

Another aspect studied was hand–eye coordination Group A children appear to lose hand–eye coordination whenever a problem or a situation becomes more complex. Motor skills of the group A child are adequate in a simple situation The child may put beads into a bottle with skilled movements But if another stimulus catches his attention his hand movements go on but they become inadequate The visual control disappears because the child looks at something different. He will now miss the opening of the bottle and the beads may spill over the table The group A child will hesitate or refuse to climb difficult places The group B child behaves differently In the bottle task he may also lose eye–hand control but he will still be able to put beads into the bottle only with slower movements He

group Clinical observations and parental reports indicated that group A children moved inadequately as soon as a situation became complex For example when they had a complicated jig saw puzzle and tried to return it a cupboard their movements became inadequate They would stumble and spill the game on the floor When picking up a toy from under the table these children bump their heads Children of subgroup B were not observed to have such difficulties

The next entry in Table VI evaluates the integration of a visual series It was pointed out earlier that children of the clinical group were deviant in anticipatory behavior when tested with the beads-tube task of the BM battery It could be observed however that children of subgroup B can learn visual anticipation in this situation When the children watched the beads being inserted into the tube and appearing again at the lower end they would learn to displace their gaze from the upper to the lower end of the tube thus demonstrating visual anticipation of a visually perceived event However they did not reach out in anticipation of the beads falling and being picked up Group A children demonstrated difficulty for either anticipation the visual or the tactile–kinesthetic type

The next item refers to the play audiometric task This time the reference is not to waiting behavior but rather to the learning of a tactile–kinesthetic response to an acoustic stimulus to put a toy down when a tone was presented The seven children of group B who could be tested learned the task only after many trials Children of group A did not have this difficulty Their failure of the audiometric task was due to a difficulty in attention span as discussed previously and not due to the absence of a tactile-kinesthetic response to an acoustic stimulus.

Another set of observations also concerns tactile–kinesthetic components but instead of being coupled with an auditory component as in audiometry coupled with a visual component The last set of observations under anticipation in Table VI is concerned with tactile–kinesthetic–visual integration Parents of children in group A often report that they seem to be over-cautious in simple situations like jumping off a wall or in going with somebody they do not know They lose control in complex situations such as crossing a street When there is only one car they can wait. But if there is much traffic they appear to lose their heads and panic

Children of group B behave differently They often run away from home Their mothers have to watch the children continually for they climb walls fences and window sills without realizing the risks they take

Group A children present mitual stupor They hesitate when they are in a new situation or when they meet somebody new Not so the group B children They don t seem to notice changes They do not scan a new situation and then adapt to it. They either do not notice change or they begin to show panic reactions Eye contact breaks down more rapidly in the children of group B than group A One of the most impressive observations is that these children do not look at you as would another child Group A children however do not differ in eye contact from normal children

Another aspect studied was hand–eye coordination Group A children appear to lose hand–eye coordination whenever a problem or a situation becomes more complex Motor skills of the group A child are adequate in a simple situation. The child may put beads into a bottle with skilled movements But if another stimulus catches his attention his hand movements go on but they become inadequate The visual control disappears because the child looks at something different. He will now miss the opening of the bottle and the beads may spill over the table The group A child will hesitate or refuse to climb difficult places The group B child behaves differently In the bottle task he may also lose eye–hand control but he will still be able to put beads into the bottle only with slower movements He

gives the impression of a blind child proceeding with tactually monitored movements without visual control Parents of subgroup B children report that they are amazed at how their children can climb in difficult places

Another aspect of interest is shifting ability Again differences have been observed between the two subgroups Reports of parents and observations in the clinic point to the group A children as being stubborn They refuse to do something for an extended period They may not speak for hours in a new situation At home parents complain how difficult it is to make them change their minds Not one of the group B children is described as stubborn When they are put into a new situation they may panic They may refuse to do something but it is easy to make them change their minds

Another feature stereotyped movements was observed exclusively in the children of subgroup B and not in children of subgroup A These are children whose hands tremble when they are tense or upset or interested in an event or object Other children spin any object they can find Some will hit their *heads bite their hands or make facial* grimaces Children of group B who have not developed speech produce stereotyped sounds like aiaiai

Another activity perhaps related to stereotyped movements is compulsive behavior Again compulsive behavior is characteristic only of children *belonging to subgroup B and* not belonging to subgroup A Some of subgroup B children collect pens or rubber bands or candles in a compulsive manner They run for these things each time they enter the clinic and know exactly where to find them Other children open and close doors with increasing speed as if in a trance

Elaborative performances

The three stages studied in elaborative performances were divided into substages according to Piaget In the sensory motor period imitative behavior was found to separate the clinical children from the normal children significantly How do the two clinical subgroups differ in this respect?

Modality specific abilities (Table VII) are *thought to be evaluated by the listening be*havior of the children Listening behavior was observed in all children who did not have a profound hearing loss and no difference was found between children of subgroups A and B The same result was found in simple matching problems involving vision Thus modality specific performance does not appear to differentiate the two groups

The next item on Table VII refers to perception in the sense of intermodality performance For example localization was described earlier as being an expression of intermodality development The results show that all of the children of subgroup A have developed such intermodality performance Three of the subgroup B children could not be tested because it was not possible to elicit reliable responses for such performances The nine who were tested failed to present localization responses It seems that the children of group B are *deviant in intermodality development*

The finding of better direct imitation and poorer deferred imitation was mentioned as being normal for direct imitation develops before deferred imitation All children of the clinical group were found to be delayed in imitation This must mean that during the *first 18 months* when a normal child acquires the ability to imitate directly none of the clinical group has done so For some of the group it appears to take several years longer to learn imitative behavior When this is the case the difference between the two subgroups becomes apparent When the children of group A begin to show imitation it is at first deferred imitation Direct imitation is learned by these children only after another time lag The children of group B are different showing the normal pattern of direct before delayed imitation Table VII points out that four of the children of group B have imitative

performance while the rest of the group could not imitate. The interesting observation however is that the four children of group B who have learned imitative behavior follow the pattern of the normal child. They first begin to imitate directly when the model is present. Only after a time lag do they begin to show deferred imitation.

In Table VII under figurative performance it can be seen that both subgroups were observed on drawing performance. Five children in subgroup A and one child in subgroup B younger than 5 years were not tested. Considering the tested children it seems from Table VII that drawing performance partially differentiates the two groups. All tested subgroup B children performed inappropriately indicating that none of the children of group B utilized graphic means of expression. However 77% of subgroup A children were regarded as appropriate having developed some drawing skills. Three were judged inappropriate. One of these just turned 5 years old the 2 other children scored at a 5 year level on intellectual development. Thus since all children of the clinical group appear to be delayed in

Table VIII Summary of results for speech sound production for the clinical group within the clinical group (numbers of subjects and percentages)

NT=not tested T=tested App =appropriate Inapp =inappropriate

Group A		Group B			Group A		Group B

drawing production it seems reasonable that these three children had not developed drawing skills yet

On picture recognition all subgroup A children appear to extract meaning from pictures while only 33% of subgroup B do so On the Borel Maisonny task used to evaluate symbolic play 86% of the children tested in subgroup A and only 17% (one subject) of subgroup B were scored as appropriate In observations of spontaneous symbolic play activities all of group A and none of group B were rated appropriate Finally the meaningfulness of speech was observed All children in subgroup A produce some sounds with meaning while only 4 of subgroup B can be heard to produce meaning It is of considerable interest to note that these four children were those whose direct-deferred imitation pattern was similar to that of normal children and those who scored appropriate for picture recognition

The final section of Table VII summarizes the results obtained on operative performance The geometric forms subtest of SON battery was used to evaluate visual sorting While 33% of subgroup A could not be tested 83% of subgroup B were unable to be tested However of the children tested roughly half of each group responded appropriately but only 2 children of subgroup B were tested

For the last item the children of group A appear to present an appropriate linearity between operative and figurative development Group B children are inappropriate in this respect They seem to be more developed in operative processes than in figurative performances However this evaluation includes only observations and not standardized procedures

It appears that localization direct versus deferred imitation patterns drawing picture recognition symbolic play and the linearity between operative and figurative development differentiate the two groups

Speech sound production

The observations on speech sound production are summarized in Table VIII In Table VIII it may be seen that 67% or 12 children of the subgroup A children and only 25% of subgroup B children could be tested This result stems from the fact that most of the children in subgroup B could not talk at all Of the children tested in the two clinical subgroups there is no percentage difference between those able to produce high frequency components One third of the tested children in both subgroups could produce clear co[illegible]

However this amounts to only one child in subgroup B

In formant clarity which should reflect normal voice quality none of subgroup B and only two children in subgroup A were found appropriate With respect to intonation 67% of subgroup A and 100% of subgroup B were found appropriate as judged from spectrographic analysis An interesting finding emerged at this point The children in subgroup A who had high frequency components tended not to be appropriate in intonation while children whose intonation was appropriate tend not to have adequate high frequency components above 3 000 Hz In short these children tend to have either clear consonants and poor intonation or poor consonants and good intonation but not both Thus the children in subgroup A appear to be successful in one aspect of speech sound production or another but not at a more complex level of both As with other performances by this group the children appear to experience difficulty with tasks of a more complex level This is not the case however with the 3 children tested in subgroup B Here only one child the most advanced of the subgroup can produce both high frequency components and adequate intonation The other 2 tested appear to be at an earlier level that is able to produce adequate intonation but not yet able to produce clear consonant In normal development of speech sound production intonation is established before clear consonant articulation is achieved (Gleason 1955 Bolinger 1962)

With respect to rate most children tested in both subgroups were adequate As for consonant clusters all productions of the children tested in subgroup A were inappropriate Thus although 33% of those tested in subgroup A could produce clear consonants none of them could produce a successive series of consonants Again one child in subgroup B the most advanced could produce consonant clusters while the other 2 could not The ability to produce consonant clusters is established after consonant articulation with the less proficient stage being marked by consonant–vowel sequences

Additional comment seems useful at this point In subgroup A 1 children were observed and all could be tested In subgroup B 11 children were observed but only 3 had sufficient speech to make spectrographic analysis meaningful Of the remaining 8 none was able to produce speech This is not to say that these 8 children could not produce sound but rather that the sounds they produced were not speech sounds The difference is great. Any audible noise can be called a sound but it is not necessarily a speech sound Speech sounds belong to a particular linguistic system and may occur only in the sequences allowed by the phonological rules of that linguistic system Prolonged observations of these 8 children of subgroup B revealed no such systematic relationship between their noise and a linguistic system One child of the 8 produced no orally emitted sounds at all during the periods of observation Thus on speech sound production children of subgroup B show a dichotomous characteristic not seen in subgroup A The subgroup B children either can produce speech sounds or they can not. If they do the less proficient will be able to produce meaningful intonation while the more proficient can produce consonants consonant clusters and intonation Thus they appear to follow a normal sequence of developmental stages Children in subgroup A will be able to produce speech sounds but will produce either clear consonants or good intonation but not both They appear unable to deal with the increasing complexity of both intonation and consonant articulation or of consonant cluster sequences

Speech sound production

The observations on speech sound production are summarized in Table VIII In Table VIII *it may be seen that 67% or 12 children of the* subgroup A children and only 25% of subgroup B children could be tested This result stems from the fact that most of the children in subgroup B could not talk at all Of the children tested in the two clinical subgroups there is no percentage difference between *those able to produce high frequency* components One third of the tested children in both subgroups could produce clear consonants

However this amounts to only one child in subgroup B

In formant clarity which should reflect normal voice quality none of subgroup B and only two children in subgroup A were found appropriate With respect to intonation 67% of subgroup A and 100% of subgroup B were found appropriate as judged from spectrographic analysis An interesting finding emerged at this point The children in subgroup A who had high frequency components tended not to be appropriate in intonation while children whose intonation was appropriate tend not to have adequate high frequency components above 3 000 Hz In short these children tend to have either clear consonants and poor intonation or poor consonants and good intonation but not both Thus the children in subgroup A appear to be successful in one aspect of speech sound production or another but not at a more complex level of both. As with other performances by this group the children appear to experience difficulty with tasks of a more complex level This is not the case however with the 3 children tested in subgroup B Here only one child the most advanced of the subgroup can produce both high frequency components and adequate intonation The other 2 tested appear to be at an earlier level that is able to produce adequate intonation but not yet able to produce clear consonants In normal development of speech sound production intonation is established before clear consonant articulation is achieved (Gleason 1955 Bolinger 1962)

With respect to rate most children tested in both subgroups were adequate As for consonant clusters all productions of the children tested in subgroup A were inappropriate Thus although 33% of those tested in subgroup A could produce clear consonants none of them could produce a successive series of consonants. Again one child in subgroup B the most advanced, could produce consonant clusters while the other 2 could not. The ability to produce consonant clusters is established after consonant articulation with the less proficient stage being marked by consonant–vowel sequences

Additional comment seems useful at this point In subgroup A 12 children were observed and all could be tested In subgroup B 11 children were observed but only 3 had sufficient speech to make spectrographic analysis meaningful Of the remaining 8 none was able to produce speech This is not to say that these 8 children could not produce sound but rather that the sounds they produced were not speech sounds The difference is great Any audible noise can be called a sound but it is not necessarily a speech sound *Speech* sounds belong to a particular linguistic system and may occur only in the sequences allowed by the phonological rules of that linguistic system Prolonged observations of these 8 children of subgroup B revealed no such systematic relationship between their noise and a linguistic system One child of the 8 produced no orally emitted sounds at all during the periods of observation Thus on speech sound production children of subgroup B show a dichotomous characteristic not seen in subgroup A. The subgroup B children either can produce speech sounds or they can not. If they do the less proficient will be able to produce meaningful intonation while the more proficient can produce consonants consonant clusters and intonation Thus they appear to follow a normal sequence of developmental stages Children in subgroup A will be able to produce speech sounds but will produce either clear consonants or good intonation but not both They appear unable to deal with the increasing complexity of both intonation and consonant articulation or of consonant cluster sequences

Summary

Two groups of 30 children ranging in age from 3 to 10 years were studied. The first was made up of normal children while the second group consisted of speech and language handicapped children. The two groups were compared on input functions, general behavior, elaborative performance and speech sound production to determine if the groups could be differentiated on any basis other than language performance. Following this between groups comparison a second comparison was made. Since the clinical group included children who seemed to lag or lack symbolic function and other children who did develop symbolic behavior a within group comparison was made to determine if the clinical group represented a homogeneous population or two subgroups.

The *Between Groups* results indicate that the normal and clinical groups could not be differentiated on the basis of input functions like auditory and visual thresholds and auditory and visual analyses of dimensions and sequences. Inappropriate and appropriate responses were obtained from both groups. As might be anticipated more children in the clinical group were deficient in input functions. In addition more members of the clinical group could not be tested on some input tasks, a finding which points to the need of more adequate testing procedures for non verbal children.

Several aspects of general behavior appeared to differentiate the two groups. The clinical group exhibited greater fluctuation in attention span and poorer hand–eye coordination on the more complex tasks or in the more difficult situations than did the normal children. In addition the clinical group had greater difficulty than the normal in anticipation and shifting behavior.

With respect to elaborative functions the clinical group lagged behind in the development of imitation characteristic of sensory motor and intuitive processes. Similarly the clinical group was retarded in language and drawing performance. Operative performances were evaluated by means of the SON sorting test or the BM puzzle items. The high rate of failure in the clinical group appears to be due to the difficulty of the clinical group in understanding the tasks rather than to inability in solving the problems. All normal children present a linear relationship between the development of figurative and operative processes. Furthermore performances of direct imitation are better than those of deferred imitation. Also direct imitation is learned first. These types of relationships appear not to be the case in the clinical group. Clinical children either are better in operative performances than in figurative performances or they are better in deferred imitation than in direct imitation.

The children tested in the clinical group were inferior to those in the normal group on speech sound production with the superiority of the normal group being greatest on the production of consonant clusters and least on intonation.

Overall the results of the between groups comparison indicate that the normal and clinical groups can be differentiated on the basis of general behavior and some elaborative functions. The differences appear to go beyond the intuitive level characteristic for the beginning of language development since imitative processes (deferred and direct imitation as well) characteristic of a prelinguistic level of development were found to be affected in the clinical group.

On the basis of clinical impr[illegible] on the clinical group was divided into [illegible] group (subgroup A) whose members appeared t[illegible] hav[illegible] symbolic

function and into another (subgroup B) whose members appeared to lag or lack, symbolic function

The *Within Group* results like those obtained in the between groups comparison indicate that input functions do not discriminate among the members of the clinical group How ever several aspects of general behavior were found to differentiate the two clinical subgroups One discriminating function was attention span Observations of the length of attention span in relation to the type of material used in testing revealed that subgroup B had a better attention span in both simple and complex tasks when the materials required only tactile–kinesthetic manipulation However if the task involved more than one modality as when an auditory or visual component was added these children experienced difficulty Their failure was due apparently to the problem created by the involvement of more than one modality Children of subgroup A on the other hand had difficulty when the situation or task became complex They did not appear to depend on the number of modalities utilized

Another discriminating function was anticipation which yielded results similar to attention span All clinical children had difficulties waiting for events to come Children of subgroup A anticipated adequately n simple tasks but started to have difficulties when the degree of complexity was increased such as when transporting easily-disassembled puzzles from one location to another Subgroup B children were less affected by complexity than subgroup A children but failed when anticipation involved more than one modality For example these children could anticipate visually when the task was *primarily visual* as in the beads-tube task of the BM-test. They failed to build up anticipatory responses when the task required a kinesthetic–visual integration such as producing tactile–kinesthetic movements when seeing a dangerous dog, or when facing a new situation or a new person. These children also presented poor eye-contact, a performance which includes more than one modality Hand–eye coordination or body–eye coordination was judged inappropriate in all clinical children. However a thorough analysis of the performances of the subgroups in different tasks involving such coordination appears to separate them. Subgroup A children have appropriate hand–eye–coordination in simple tasks They lose coordination as soon as the tasks become more difficult. This observation can be made in any task involving hand–eye coordination by handling objects or performing motor activites The subgroup B children do not seem to depend on such a complexity factor They appear to depend more on the type of task. For example they cannot monitor visually objects as parts of a difficult task like a jig-saw board whose problem is above the performance limits of the child However they are very skilled in complex movements like climbing fences trees The suggestion is made that in the jig-saw task more than one modality is involved the visual and the tactile ones but not so in climbing. Climbing can be done by tactile contact with the object to climb Besides attention span anticipatory behavior and hand–eye coordination shifting performances appear to separate the two groups Clinical and parental reports point to subgroup A children as being stubborn but not the subgroup B children. Subgroup B children may panic in new situations or refuse a task. But it appears to be easy to change their minds. However subgroup B children present stereotype movements like biting their hands spinning objects In addition they present compulsive behavior like collecting pens rubber bands Subgroup A children do not produce such stereotype movements

Aspects of elaborative performance also discriminate between the clinical subgroups The differences are not found in modality specific processes like listening behavior or simple visual matching tasks thus corroborat

Summary

Two groups of 30 children ranging in age from 3 to 10 years were studied. The first was made up of normal children while the second group consisted of *speech and language handicapped* children. The two groups were compared on input functions, general behavior, elaborative performance and speech sound production to determine if the groups could be differentiated on any basis other than language performance. Following this between groups comparison a second comparison was made. Since the clinical group included children who seemed to lag or lack symbolic function and other children who did develop symbolic behavior a within group comparison was made to determine if *the clinical group represented a homogeneous population or two subgroups*.

The *Between Groups* results indicate that the normal and clinical groups could not be differentiated on the basis of input functions like auditory and visual thresholds and auditory and visual analyses of dimensions and sequences. Inappropriate and appropriate responses were obtained from both groups. As might be anticipated, more children in the clinical group were deficient in input functions. In addition, more members of the clinical group could not be tested on some input tasks, a finding which points to the need of more adequate testing procedures for non verbal children.

Several aspects of general behavior appeared to differentiate the two groups. The clinical group exhibited greater fluctuation in attention span and poorer hand–eye coordination on the more complex tasks or in the more difficult situations than did the normal children. In addition, the clinical group had greater difficulty than the normal in anticipation and shifting behavior.

With respect to elaborative functions, the clinical group lagged behind in the development of imitation, characteristic of sensory motor and intuitive processes. Similarly, the clinical group was retarded in language and drawing performance. Operative performances were evaluated by means of the SON sorting test or the BM puzzle items. The high rate of failure in the clinical group appears to be due to the difficulty of the clinical group in understanding the tasks rather than to inability in solving the problems. *All* normal children present a linear relationship between the development of figurative and operative processes. Furthermore, performances of direct imitation are better than those of deferred imitation. *Also, direct imitation is learned first*. These types of relationships appear not to be the case in the clinical group. Clinical children either are better in operative performances than in figurative performances or they are better in deferred imitation than in direct imitation.

The children tested in the clinical group were inferior to those in the normal group on speech sound production, with the superiority of the normal group being greatest on the production of consonant clusters and least on intonation.

Overall, the results of the between groups comparison indicate that the normal and clinical groups can be differentiated on the *basis of general behavior and some elaborative* functions. The differences appear to go beyond the intuitive level, characteristic for the beginning of language development, since imitative processes, deferred and direct imitation as well, characteristic of a prelinguistic level of development, were found to be affected in the clinical group.

On the basis of clinical impressions the clinical group was divided into one group (subgroup A) whose members appeared to have symbolic

function and into another (subgroup B) whose members appeared to lag or lack symbolic function

The *Within Group* results like those obtained in the between groups comparison indicate that input functions do not discriminate among the members of the clinical group However several aspects of general behavior were found to differentiate the two clinical subgroups One discriminating function was attention span Observations of the length of attention span in relation to the type of material used in testing revealed that subgroup B had a better attention span in both simple and complex tasks when the materials required only tactile–kinesthetic manipulation However if the task involved more than one modality as when an auditory or visual component was added these children experienced difficulty Their failure was due apparently to the problem created by the involvement of more than one modality Children of subgroup A on the other hand had difficulty when the situation or task became complex They did not appear to depend on the number of modalities utilized

Another discriminating function was anticipation which yielded results similar to attention span. All clinical children had difficulties waiting for events to come Children of subgroup A anticipated adequately *in simple* tasks but started to have difficulties when the degree of complexity was increased such as when transporting easily-disassembled puzzles from one location to another Subgroup B children were less affected by complexity than subgroup A children but failed when anticipation involved more than one modality For example these children could anticipate visually when the task was primarily visual as in the beads-tube task of the BM-test. They failed to build up anticipatory responses when the task required a kinesthetic–visual integration such as producing tactile–kinesthetic movements when seeing a dangerous dog, or when facing a new situation or a new person. These children also presented poor eye-contact a performance which includes more than one modality Hand-eye coordination or body-eye coordination was judged inappropriate in all clinical children. However a thorough analysis of the performances of the subgroups in different tasks involving such coordination appears to separate them Subgroup A children have appropriate hand-eye-coordination in simple tasks They lose coordination as soon as the tasks become more difficult. This observation can be made in any task involving hand-eye coordination by handling objects or performing motor activites The subgroup B children do not seem to depend on such a complexity factor They appear to depend more on the type of task For example they cannot monitor visually objects as parts of a difficult task like a jig-saw board whose problem is above the performance limits of the child However they are very skilled in complex movements like climbing fences trees The suggestion is made that in the jig-saw task more than one modality is involved the visual and the tactile ones but not so in climbing. Climbing can be done by tactile contact with the object to climb Besides attention span anticipatory behavior and hand-eye coordination shifting performances appear to separate the two groups Clinical and parental reports point to subgroup A children as being stubborn but not the subgroup B children Subgroup B children may panic in new situations or refuse a task. But it appears to be easy to change their minds. However subgroup B children present stereotype movements like biting their hands spinning objects In addition they present compulsive behavior like collecting pens, rubber bands Subgroup A children do not produce such stereotype movements

Aspects of elaborative performance also discriminate between the clinical subgroups The differences are not found in modality specific processes like listening behavior or simple visual matching tasks thus corroborat

Summary

Two groups of 30 children ranging in age from 3 to 10 years were studied The first was made up of normal children while the second group consisted of speech and language handicapped children The two groups were compared on input functions general behavior elaborative performance and speech sound production to determine if the groups could be differentiated on any basis other than language performance Following this between groups comparison a second comparison was made Since the clinical group included children who seemed to lag or lack symbolic function and other children who did develop symbolic behavior a within group comparison was made to determine if the clinical group represented a homogeneous population or two subgroups

The *Between Groups* results indicate that the normal and clinical groups could not be differentiated on the basis of input functions like auditory and visual thresholds and auditory and visual analyses of dimensions and sequences Inappropriate and appropriate responses were obtained from both groups As might be anticipated more children in the clinical group were deficient in input functions In addition more members of the clinical group could not be tested on some input tasks a finding which points to the need of more adequate testing procedures for non verbal children

Several aspects of general behavior appeared to differentiate the two groups The clinical group exhibited greater fluctuation in attention span and poorer hand–eye coordination on the more complex tasks or in the more difficult situations than did the normal children In addition the clinical group had greater difficulty than the normal in anticipation and shifting behavior

With respect to elaborative functions the clinical group lagged behind in the development of imitation characteristic of sensory motor and intuitive processes Similarly the clinical group was retarded in language and drawing performance Operative performances were evaluated by means of the SON sorting test or the BM puzzle items The high rate of failure in the clinical group appears to be due to the difficulty of the clinical group in understanding the tasks rather than to inability in solving the problems All normal children present a linear relationship between the development of figurative and operative processes Furthermore performances of direct imitation are better than those of deferred imitation Also direct imitation is learned first These types of relationships appear not to be the case in the clinical group Clinical children either are better in operative performances than in figurative performances or they are better in deferred imitation than in direct imitation

The children tested in the clinical group were inferior to those in the normal group on speech sound production with the superiority of the normal group being greatest on the production of consonant clusters and least on intonation

Overall the results of the between groups comparison indicate that the normal and clinical groups can be differentiated on the basis of general behavior and some elaborative functions The differences appear to go beyond the intuitive level characteristic for the beginning of language development since imitative processes deferred and direct imitation as well characteristic of a prelinguistic level of development were found to be affected in the clinical group

On the basis of clinical impressions the clinical group was divided into one group (subgroup A) whose members appeared to have symbolic

one modality These findings support the tentative conclusion that subgroup A children have a disturbance in the integration of successive stimuli when a critical level is exceeded and that subgroup B children have a disturbance in the integration of several sensory modalities

Turning now to the results of this study concerning elaborative function group A children appear to have developed intermodality coordination but have failed on the next level that of direct imitation Inasmuch as Piaget has indicated that success of direct imitation involves not only integration of visual–tactile–kinesthetic or auditory–tactile–kinesthetic modalities but also sequential integration of successive stimuli the tentative conclusion may be advanced that group A children fail direct imitation because they cannot integrate successive stimuli in time Inasmuch as most of the children of subgroup B do not develop imitation their problem seems to be due to a failure in the development of the required intermodality coordination. Once this coordination is developed the child will proceed in the normal sequence of direct imitation followed by deferred imitation.

In regard to figurative processes subgroup B children are found to lag in symbolic development It may be inferred that this failure is due to lack of development of intermodality coordination characteristic of a lower level of development This supports the tentative conclusion that intermodality coordination is a prerequisite for symbolic function Subgroup A children have developed intermodality processes and symbolic function which allows the tentative conclusion that sequential integration is not a prerequisite for symbolic function Inasmuch as subgroup A children have difficulties in figurative performances such as drawing and speaking it would seem to support the tentative conclusion that these activities require an extensive degree of sequential integration

Finally speech sound analysis of the children of subgroup B revealed that eight of these children failed to produce speech sounds These same children failed figurative performances completely such as picture recognition symbolic play imitation drawing Only four of group B children produce speech These children do localize recognize pictures imitate directly Their imitation follows a normal sequence first direct imitation Their speech sound production also follows a normal sequence 3 of the children have correct intonation but not correct consonants Only one the least damaged child of group B has both correct intonation and correct consonants It seems therefore that once a critical amount of intermodality schemes have developed the child of group B will begin to imitate will then develop symbolic processes and learn to produce speech sounds in a normal sequence The speech sound analysis of the subgroup A children also supports the findings of general and elaborative behavior They either can produce intonation correctly or the consonants but not both This seems to support the complexity dependency of these children They appear to integrate only a reduced amount of stimuli at a time and thus fail to control a critical amount of sequential stimuli.

In summary the clinical group of severely language handicapped children of this study presents two subgroups of children The primary difficulty of subgroup A children appears to include a level of sequential integration The subgroup B children appear to have difficulty on an intermodality level of perception which seems to develop primary to symbolic and language acquisition The hypothesis can be advanced that a critical amount of intermodality connection is necessary for imitation for symbolic processes and for language acquisition A critical amount of sequential integration is a prerequisite for direct imitation and speech sound production.

ing the results obtained on input performances which are of a modality specific kind too The differences are found in more complex perceptual activities Most of the subgroup B children failed intermodality tasks such as localizing an acoustic signal Only the least damaged of the subgroup B children four subjects presented localization behavior All children of subgroup A presented appropriate intermodality performances However subgroup A children were inappropriate in the relationship between direct and deferred imitation Normal children and children of subgroup B who had developed imitation show better performance in direct imitation than in deferred imitation None of the subgroup A children present this type of relationship During the time the normal child acquires direct imitation subgroup A children appear to lack such behavior By the time the normal child develops deferred imitation the subgroup A child also begins to develop deferred imitation but will still lack direct imitation *Figurative performances strongly differentiate* the two subgroups All clinical children are delayed in drawing performances However subgroup A children appear to learn to draw after a delay They recognize pictures and play *symbolically* Subgroup B children are different None of them had any graphic means of expression They all lack symbolic play Only four of the subgroup B children recognize pictures and produce speech sounds with meaning

A comparison between operative processes and figurative processes indicates that subgroup A children seem to develop both types of processes in a linear relationship Subgroup B children are different They lag or even lack completely figurative processes but not operative processes Their operative performances present a higher level of development than figurative processes This corroborates the clinical impressions of a lag of symbolic performances in the clinical subgroup B

In regard to speech sound production all children of subgroup A had this ability but only *four of the subgroup B children* However productions of subgroup A were characterized by an either–or aspect of being able to produce consonants or to produce intonation but not both simultaneously In *distinction the four subgroup B children* who had speech sounds first have intonation while the most advanced has both intonation and consonants This is the normal sequence of acquisition

Conclusion

From the results of this study it appears that severely speech and language handicapped children can be *distinguished from normal* children not only on the basis of their language difficulties *but also on the basis of their* general behavior elaborative function and speech sound production The differences *point to a disturbance primary to language* acquisition affecting sensory-motor performances in Piaget s meaning Modality specific input functions were not found to be an adequate basis upon which to distinguish the clinical from the normal group

The severely speech and language handicapped children studied here were not a homogeneous group but were found to represent two subgroups which *differ* in several respects

In general behavior it was found that subgroup A children fail when tasks involve a critical degree of complexity Subgroup B children fail when tasks involve more than

Introduction

Today one may with a high degree of accuracy maintain that the efforts of the ear nose-throat surgeons have solved the problem of the surgical treatment of otosclerosis (Chevance et al 1970) This assertion provides a good picture of the gap which exists between the surgeons successes and our biological understanding of the disease Why is it so rare among the Japanese and the Orientals while being frequent among members of the Caucasian and American-Indian races? (Sakai 1971) Why are there so many otosclerotic foci in a random histological material while so few get clinical symptoms of this disease? (Engström 1939) The works of Engström from 1939 and 1940 raised questions which are still of current interest but which cannot be answered until as a background we have available epidemiological studies of the distribution of the disease in countries where medical treatment is so readily available that reliable statistics can be derived because we may expect most individuals with clinical symptoms to undergo medical examination Larsson (1960) states

In view of the effective surgical methods of treatment now adopted most otosclerosis patients will sooner or later seek medical advice because of reduced hearing. As shown later this may not be quite true In countries such as the Scandinavian where the ear nose and throat departments have every technical facility to diagnose the disease one might expect that these patients would always be directed to a hospital where the efficacy of surgical treatment can be estimated Concerning Norway this expectation may also not hold true

The purpose of this study is to consider the geographical distribution and the possible inherited tendency of otosclerosis in Norway and to provide a survey of the number of Norwegians suffering from otosclerosis in this country

Studies of similar character are not numerous The above mentioned paper of Larsson is a genetic study of the occurrence of the disease in the families of 262 otosclerosis patients and it may serve as a model for similar heredity studies Larsson did not aim at giving a survey of the geographical distribution of otosclerosis in Sweden Among his findings one might emphasize the fact that there were twice as many women as men among the probands whereas among their closest relatives i.e. parents brothers and sisters of the patients 8 6 per cent were men and 11.5 per cent women, thus a much smaller and not statistically significant predominance of women Larsson states that 80 per cent of the patients information about otosclerosis within the family were true Furthermore he stated that most of the cases which came to treatment were between 11 and 42 years of age

Shambaugh Jr described in 1949 his experience from 2 100 patients who had been operated by the "old" method fenestration He indicated that the disease strikes 0.5 to 1 per cent of the white population, that the loss of hearing normally starts about the age of 20 and only in rare cases during childhood and that the ratio of women to men is 3 2

Ballantyne in his book Deafness (1960) sums up the general facts about otosclerosis now accepted in most textbooks The loss of hearing is usually noticed during the teens or early twenties and twice as often among females than among males In half of the cases also another member of the family suffers from a similar loss of hearing, and usually the

Introduction

Today one may with a high degree of accuracy maintain that the efforts of the ear nose throat surgeons have solved the problem of the surgical treatment of otosclerosis (Chevance et al 1970) This assertion provides a good picture of the gap which exists between the surgeons successes and our biological understanding of the disease. Why is it so rare among the Japanese and the Orientals while being frequent among members of the Caucasian and American Indian races? (Sakai 1973) Why are there so many otosclerotic foci in a random histological material while so few get clinical symptoms of this disease? (Engström 1939) The works of Engström from 1939 and 1940 raised questions which are still of current interest but which cannot be answered until as a background we have available epidemiological studies of the distribution of the disease in countries where medical treatment is so readily available that reliable statistics can be derived because we may expect most individuals with clinical symptoms to undergo medical examination. Larsson (1960) states In view of the effective surgical methods of treatment now adopted most otosclerosis patients will sooner or later seek medical advice because of reduced hearing. As shown later this may not be quite true In countries such as the Scandinavian, where the ear nose and throat departments have every technical facility to diagnose the disease, one might expect that these patients would always be directed to a hospital where the efficacy of surgical treatment can be estimated Concerning Norway this expectation may also not hold true

The purpose of this study is to consider the geographical distribution and the possible inherited tendency of otosclerosis in Norway and to provide a survey of the number of Norwegians suffering from otosclerosis in this country

Studies of similar character are not numerous The above mentioned paper of Larsson is a genetic study of the occurrence of the disease in the families of 262 otosclerosis patients and it may serve as a model for similar heredity studies Larsson did not aim at giving a survey of the geographical distribution of otosclerosis in Sweden. Among his findings one might emphasize the fact that there were twice as many women as men among the probands whereas among their closest relatives i.e. parents brothers and sisters of the patients 8 6 per cent were men and 11.5 per cent women thus a much smaller and not statistically significant predominance of women Larsson states that 80 per cent of the patients information about otosclerosis within the family were true Furthermore he stated that most of the cases which came to treatment were between 11 and 42 years of age

Shambaugh Jr described in 1949 his experience from 2 100 patients who had been operated by the "old" method fenestration He indicated that the disease strikes 0.5 to 1 per cent of the white population, that the loss of hearing normally starts about the age of 20 and only in rare cases during childhood and that the ratio of women to men is 3 2

Ballantyne in his book Deafness (1960) sums up the general facts about otosclerosis now accepted in most textbooks The loss of hearing is usually noticed during the teens or early twenties and twice as often among females than among males In half of the cases also another member of the family suffers from a similar loss of hearing, and usually the

hearing loss in women seems to be aggravated during pregnancy No one knows the cause of this If the disease makes its debut during pregnancy it may be attributable to some hormonal cause while its familial occurrence indicates hereditary factors

Altman et al (1967) gives a survey of the histological material of otosclerosis until 1967 A total of 4 662 patients with otosclerosis are involved From this material we draw the following conclusions Otosclerosis is a hereditary disease frequent among Caucasians (whites and East Indians) but very rare among negroes and people of Mongolian descent (Japanese Indonesians Chinese American Indians) This distribution may suggest that the disease originally started through a genetical mutation The fact that it is so rare among Mongols and so frequent among Americans but not among American Negroes may be due to the fact that there has not been much interbreeding between these races The dominance among women is difficult to explain Moreover the authors emphasize their lack of reliable data concerning the distribution of otosclerosis in different races particularly among negroes living in the U S Therefore their assertions are under correction The authors state that in autopsies from the white population otosclerosis is found histologically in 8 3 per cent while only 0 99 per cent have stapes fixation In both cases the ratio of women to men is like 7 6 Among Negroes in the U S particularly in New York otosclerosis seems histologically to be seven times rarer than among whites but the authors consider the sample of Negroes examined previous to 1967 as too small and also the low number of clinically diagnosed otosclerosis in negroes may be due to their general lack of access to medical service

Davis & Silverman (1970) in their book Hearing and Deafness present the data on otosclerosis which by then were commonly accepted Otosclerosis causes stapes fixation and loss of hearing only in approximately 10 per cent of those cases in which it occurs histologically The hereditary factor exists in all persons with histological otosclerosis but those who manifest clinical symptoms are the least fortunate ones in a much larger group of carriers of the gene This may explain why loss of hearing may not occur in one or more generations of a family with this inherited tendency despite the fact that the disease usually is considered as autosomal dominant hereditary without complete manifestations

Sakai (1971) states from Japan that until December 1971 he had seen only 197 cases of otosclerosis in the otological department of Keio University There was no significant difference between men and women and progressive loss of hearing among family members was found only in 20 per cent of the cases

Morrison (1967) examines the literature on otosclerosis from 1938 and onwards concluding as follows Otosclerosis is a disease that occurs only in man and principally among people of Caucasian descent It is a very frequent cause of deafness in Europe Balkan Middle East and India and among the whites of North- and South America Australia New Zealand and South Africa It occurs also in Malaya New Guinea the Philippines and in Japan then among people of mixed race of Mongolians Negroes and Ainu (people from Hokkaido the Kurils Sakkalin) It is rarely seen among pure Mongols and Negroes It is found among the Negro population of America and the West Indies although ten times as rarely there as among people of the Caucasian race Morrison obtains his data on otosclerosis from a study of 150 probands and their families and arrives at the following conclusions Clinical otosclerosis occurs in 0 3 per cent of the population in England in 91 per cent of the cases it starts between 15 and 45 years of age in 2 per cent under 10 years in 3 per cent between 10 and 15 years and in 4 per cent above 45 years This age distribution is identical for both men and women The author also discusses the widespread opinion that the disease is twice as frequent among women as among men believing that

this assumption does not stand up to closer examination In the first place there are more women than men in the populations which have been studied and women are also more inclined to consult a doctor Secondly unilateral otosclerosis and asymmetric deafness is much more frequent among men (70 per cent as compared to 9) Thirdly the attention of men is not so easily attracted to their disease as they are living and working in more noisy conditions They may have a neurogenic loss of hearing concealing a possible otosclerosis Fourthly the hormonal influence during pregnancy may tend to increase the hearing loss in women Concerning this last assumption, Morrison states that in 12 per cent of all women suffering from otosclerosis the hearing loss was the first symptom to be discovered and in a further 42 per cent the loss was aggravated during pregnancy The reason may be the osteoporosis occurring during pregnancy and lactation The heredity seems to be dominant in some families where it follows the Mendelian laws In other families with this inherited tendency however otosclerosis occurs only in 10 per cent of the expected number because some family members merely become carriers of the disease and do not show its clinical manifestations. These may however transfer clinically manifest otosclerosis to the next generation

Many authors (e g Morrison 1967 Morrison & Bundley 1970) discuss the question of whether there is a common cause in both osteogenesis imperfecta (van der Hoeve de Kleyn s syndrome) and otosclerosis They conclude that there is no proof that these diseases are due to the same anomalous mutation, but they belong to the same family of inherited collagen anomalies The deafness caused by osteogenesis imperfecta is described as a genocopy of otosclerosis" In Norway too this question has been a subject of interest Opheim described in 1968 five operated cases Hall & Röhrt (1968) studied the stapes histologically in one case and so did Hall & Lexow in 1973 (in preparation) In these studies the histological findings were very similar in the two diseases but the fragile fibrous stapes crurae seen in osteogenesis imperfecta were not like the otosclerotic ones

Material

The records of patients with the clinical diagnosis otosclerosis during the decade 1960–1969 were examined In this period otosclerosis operations were performed in the E N T departments of Rikshospitalet and Ullevål Sykehus, Oslo and in the cities Bergen Namsos Bodø and Tromsø Initially an inquiry was sent to the remaining E N T -departments in the country They all stated that every case of otosclerosis had been referred to one of the above mentioned clinics A study of otosclerosis among the Lapp population was also planned but it became apparent that this would require a separate study including a family anamnesis and an audiometrical study of a substantial number of Lapps Practical difficulties led to temporary postponement of such a study as the Lapps do not join in great numbers except when gathering their reindeer for slaughtering, a time when one cannot expect them to participate in anything else. However it was confirmed that otosclerosis exists among Lapps (see the discussion)

The information obtained from the files was recorded on a form containing columns for sex age familial inheritance therapeutic measures, place of birth and residence (Fig. 1) One form was filled out for each patient, 2066 persons in all on the basis of the records from the departments in question during the decade 1960–1969 This period gave no correct impression of the total capacity of the

hearing loss in women seems to be aggravated during pregnancy No one knows the cause of this If the disease makes its debut during pregnancy it may be attributable to some hormonal cause while its familial occurrence indicates hereditary factors

Altman et al (1967) gives a survey of the histological material of otosclerosis until 1967 A total of 4 662 patients with otosclerosis are involved From this material we draw the following conclusions Otosclerosis is a hereditary disease frequent among Caucasians (whites and East Indians) but very rare among negroes and people of Mongolian descent (Japanese Indonesians Chinese American Indians) This distribution may suggest that the disease originally started through a genetical mutation The fact that it is so rare among Mongols and so frequent among Americans but not among American Negroes may be due to the fact that there has not been much interbreeding between these races The dominance among women is difficult to explain Moreover the authors emphasize their lack of reliable data concerning the distribution of otosclerosis in different races particularly among negroes living in the U S Therefore their assertions are under correction The authors state that in autopsies from the white population otosclerosis is found histologically in 8 3 per cent while only 0 99 per cent have stapes fixation In both cases the ratio of women to men is like 7 6 Among Negroes in the U S particularly in New York otosclerosis seems histologically to be seven times rarer than among whites but the authors consider the sample of Negroes examined previous to 1967 as too small and also the low number of clinically diagnosed otosclerosis in negroes may be due to their general lack of access to medical service

Davis & Silverman (1970) in their book Hearing and Deafness present the data on otosclerosis which by then were commonly accepted Otosclerosis causes stapes fixation and loss of hearing only in approximately 10 per cent of those cases in which it occurs histologically The hereditary factor exists in all persons with histological otosclerosis but those who manifest clinical symptoms are the least fortunate ones in a much larger group of carriers of the gene This may explain why loss of hearing may not occur in one or more generations of a family with this inherited tendency despite the fact that the disease usually is considered as autosomal dominant hereditary without complete manifestations

Sakai (1971) states from Japan that until December 1971 he had seen only 197 cases of otosclerosis in the otological department of Keio University There was no significant difference between men and women and progressive loss of hearing among family members was found only in 20 per cent of the cases

Results

Distribution of the material according to sex and county

Fig 3 gives a survey of the number of patients with the diagnosis otosclerosis derived from the respective departments It also shows the ratio of men to women Rikshospitalet had the greatest number of patients 693 followed by Bergen with 597 It appears from the tables that the figures are somewhat fluctuating During the years 1963–1967 the number of cases was high in all departments This circum stance will be discussed later The proportion of men to women at Rikshospitalet and in Bergen was approximately 3 5 at Ullevål 1 2, in Namsos 2 3 in Bodø 3 4 and in Tromsø 1 1 The average proportion of men to women is 3 Fig 4 shows the distribution of cases in our different counties in proportion to their population The population numbers obtained from the Central Bureau of Statistics are from the year 1965 which is the middle of the period concerned

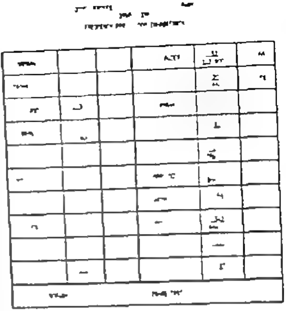

Fig 4 The number of cases seen in proportion to the total population gives the frequency withi each county

Geographical distribution

Data on place of birth and residence (Fig 5) and on the patients shift of residence, were taken from the cover of the records A total of 822 or approximately 40 per cent had moved from their birth-place However the distribution of the disease according to coun ties and geographical position turned out to be identical whether one calculated according to their place of birth or their residence as shown in Fig. 5 This point was statistically verified by taking the addresses of 50 patients who had moved and distributing these to the counties representing their new residen e No statistically significant difference emerged in the distribution of patients in the various counties Most moves are intra-county and not inter-county

macro flowchart is designed which broadly outlines those operations and calculations the computer has to carry out to give the wanted information from the material On the basis of this a micro flow-chart is designed which in detail tells the computer each single step to be performed while carrying out the different calculations In this case these consisted of accumulations of and tests on the different criteria These were then translated to a Fortran code (I e a language understandable by the computer) and punched

The program was first tested in the computer with a limited number of cards The result was controlled by hand to see if it was in accordance with the answers wanted from the different criteria The questions asked to the computer are shown in Fig 2 The results appear on data lists they are transferred to forms as shown in the figures seen later

various departments because otosclerosis surgery was not performed before 1961 in Bergen and not before 1967 in Tromso However the distribution seen on a national scale was probably not affected by this as the patients from these departments were previously directed elsewhere They have therefore been recorded as belonging to the department into which they were admitted

The data processing procedure

The data from each form were later punched on cards after the elaboration of card headings and flow-charts By means of flow-charts one may find out which classifications must be performed before the different data within each group can be listed one by one and in combinations Then a program for the machine must be made Starting from the collected data and the questions one wants answered a

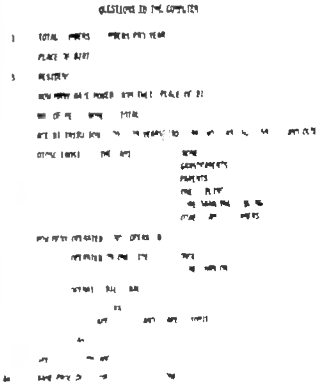

Fig 2

Results

Distribution of the material according to sex and county

Fig. 3 gives a survey of the number of patients with the diagnosis otosclerosis derived from the respective departments. It also shows the ratio of men to women. Rikshospitalet had the greatest number of patients, 693, followed by Bergen with 597. It appears from the tables that the figures are somewhat fluctuating. During the years 1963–1967 the number of cases was high in all departments. This circumstance will be discussed later. The proportion of men to women at Rikshospitalet and in Bergen was approximately 3 : 5, at Ullevål 1 : 2, in Namsos 2 : 3, in Bodø 3 : 4 and in Tromsø 1 : 1. The average proportion of men to women is 2 : 3. Fig. 4 shows the distribution of cases in our different counties in proportion to their population. The population numbers obtained from the Central Bureau of Statistics are from the year 1965, which is the middle of the period concerned.

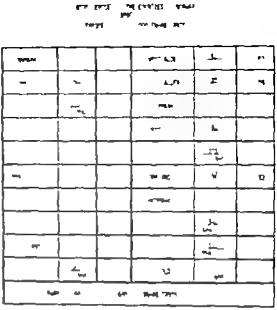

Fig. 4. The number of cases seen in proportion to the total population gives the frequency within each county.

Geographical distribution

Data on place of birth and residence (Fig. 5) and on the patients' shift of residence, were taken from the cover of the records. A total of 822 or approximately 40 per cent had moved from their birth-place. However, the distribution of the disease according to counties and geographical position turned out to be identical whether one calculated according to their place of birth or their residence as shown in Fig. 5. This point was statistically verified by taking the addresses of 50 patients who had moved and distributing these to the counties representing their new residence. No statistically significant difference emerged in the distribution of patients in the various counties. Most moves are intra-county and not inter-county.

various departments, because otosclerosis surgery was not performed before 1961 in Bergen and not before 1967 in Tromsø. However the distribution seen on a national scale was probably not affected by this as the patients from these departments were previously directed elsewhere. They have therefore been recorded as belonging to the department into which they were admitted.

The data processing procedure

The data from each form were later punched on cards after the elaboration of card headings and flow-charts. By means of flow-charts one may find out which classifications must be performed before the different data within each group can be listed one by one and in combinations. Then a program for the machine must be made. Starting from the collected data and the questions one wants answered a macro flowchart is designed which broadly outlines those operations and calculations the computer has to carry out to give the wanted information from the material. On the basis of this a micro flow-chart is designed which in detail tells the computer each single step to be performed while carrying out the different calculations. In this case these consisted of accumulations of and tests on the different criteria. These were then translated to a Fortran code (i.e. a language understandable by the computer) and punched.

The program was first tested in the computer with a limited number of cards. The result was controlled by hand to see if it was in accordance with the answers wanted from the different criteria. The questions asked to the computer are shown in Fig. 2. The results appear on data lists; they are transferred to forms as shown in the figures seen later.

Fig 8

The two maps of Southern and Northern Norway (Figs 6 and 7) clearly reflect the fact that the number of cases is proportionate to the density of population The somewhat uneven distribution in densely populated areas will be discussed later

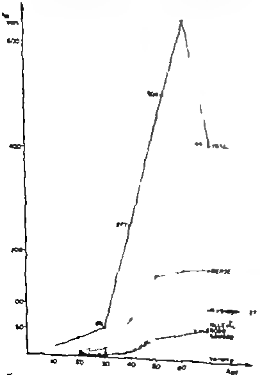

Fig 9

Age distribution

The age distribution appears from Figs 8 and 9 The greatest number of patients were within the group 50–59 years totalling 714 cases or 35 per cent. Furthermore one notes that 477 cases or 23 per cent were older than 60 years and 31 or 1.5 per cent younger than 20 Besides it is remarkable that at Rikshospitalet the largest group was the one between 40 and 49 years whereas the greatest number of patients both in Bergen and Tromsø were older than 60 The reason an accumulation of patients in certain districts will be discussed later The age distribution is also shown in a diagram (Fig. 9) in order to facilitate a general survey

Heredity

The concept of familial occurrence in otosclerosis is well accepted among otologists and further confirmed by the records investigated in the present study If no other member of the family had this disease this point was al

A survey of the hearing loss reported within the families is given in Fig 12. This table must be read crosswise vertically/horizontally e.g. how many patients stated that their grandparents and/or more far-off relatives had a reduced hearing is shown in the top right hand corner

Operations

It was not the purpose of this study to state the results or the achieved improvement in hearing after surgery However it was of interest to compare the number of operations performed to the number of diagnosed clinical otoscleroses To a certain extent such a survey (Fig 13) reveals how adequate Norwegian otologists find the present surgical technique. The figure gives an idea of the difference in opinion as to the selection of patients for operation, and about the indications for operation maintained in the various departments These questions will be discussed later

It was also interesting to see how many patients had been operated *bilaterally* and how many had been operated by the old method fenestration which is today considered out moded Fig 14 shows all the operations performed on the patients including those before 1960 1388 patients were operated once 137 were operated more than once on the same side usually a stapediolysis the first time and a stapedectomy secondly or a reoperation either to correct the position of the prosthesis or to renew it. 435 were operated bilaterally Among these 148 came from Rikshospitalet

ways marked in the files Fig 10 shows that 51 per cent of the patients had relatives with reduced hearing and 1017 or 49 per cent did not However by comparing the results from the various departments with each other it was revealed that the extent to which the patients were questioned was not the same in all hospitals For instance among the patients at Ullevål 80 3 per cent reported the presence of family members with a hearing loss whereas in Tromsø only 32 per cent This may be a true difference or the result of inadequate questioning in the latter hospital Fig. 11 shows the distribution of hearing loss among parents grandparents siblings and more remote relatives Among the total of 2066 persons 113 stated that one of their grandparents had a reduced hearing It may be deduced (see Discussion) that 0 3 per cent of the Norwegian population have otosclerosis whereas the corresponding figure for the patients grandparents is 1 4 per cent 515 of the 2066 patients stated that one of their parents also suffered from reduced hearing which represents 12 5 per cent Thus considerably higher figures are found for the relatives of otosclerotics than among the rest of the population Unfortunately it was impossible to calculate corresponding figures for siblings as the records did not tell how many brothers and sisters there were However if one considers hypothetically the possibility that they had one two or three brothers or sisters of whom one was suffering from a hearing loss the figures can be calculated to 13 2 4 4 and 3 3 per cent respectively If they had two or three brothers or sisters and two or more of these also were suffering from hearing loss the figures would be 2 5 and 1 9 per cent respectively which proves that also among brothers and sisters hearing loss is considerably more frequent than among the rest of the population (0 3%)

Fig 12

A survey of the hearing loss reported within the families is given in Fig 12. This table must be read crosswise vertically/horizontally e.g. how many patients stated that their grandparents and/or more far-off relatives had a reduced hearing is shown in the top right hand corner

Operations

It was not the purpose of this study to state the results or the achieved improvement in hearing after surgery However it was of interest to compare the number of operations performed to the number of diagnosed clinical otoscleroses To a certain extent such a survey (Fig 13) reveals how adequate Norwegian otologists find the present surgical technique The figure gives an idea of the difference in opinion as to the selection of patients for operation, and about the indications for operation maintained in the various departments These questions will be discussed later

It was also interesting to see how many patients had been operated bilaterally and how many had been operated by the old method fenestration which is today considered out moded Fig 14 shows all the operations performed on the patients including those before 1960 1388 patients were operated once 137 were operated more than once on the same side usually a stapediolysis the first time and a stapedectomy secondly or a reoperation either to correct the position of the prosthesis or to renew it. 435 were operated bilaterally Among these 148 came from Rikshospitalet

Discussion

General remarks

The primary object of this study was to provide a survey of the geographical distribution of otosclerosis in Norway. As this approach involved the necessity of examining the records of every single patient, the task was enlarged so as to include also the distribution according to sex and age, familial hardness of hearing, operations and the distribution of hearing aids. However, it must be pointed out that several reservations must be applied to a study of this kind.

As for the geographical distribution, we have found no comparable figures from other countries, since other studies have concentrated mainly on histological problems (Engström 1939), genetic ones (Larsson 1960) or racial aspects (Altmann et al. 1967, Morrison, 1971). As stated in the section "Material", we originally planned to include a statistical survey of otosclerosis among the Lapps. This question was discussed with the otologist in Tromsø (I. Marr) who had previously contacted the chief physicians of Luleå and Oulu, the northern districts in Sweden and Finland with a Lapp population. None had seen otosclerosis in Lapps. However, at Rikshospitalet a 40-year-old reindeer-owner was operated on by O. Opheim in 1956. At the Bodø clinic, A. Gulsvik performed one operation in 1968, and in 1971 I. Marr also performed a stapedectomy on a Lapp, and had the foot plate histologically examined. These three cases prove that otosclerosis also occurs in Lapps.

Concerning the data on the number of patients, geographical, sex and age distribution, hearing aids, noise exposition and the influence of pregnancy, it is assumed that the presented data are reliable and complete. As for the familial occurrence one had to rely upon the patients' own report of their family members' state of hearing, and such statements are subject to inaccuracies.

Another objection to this study is that it hardly comprises all cases in this country, only those who have been seen and diagnosed by a doctor. Of course, there are some patients suffering from otosclerosis who never become hospitalized, e.g. because they have another and more serious disease which prevents them from undergoing surgery, or they do not consult a doctor because they do not know or believe that anything can be done for them. They may have a long distance to the doctor, fear of operations, or they have never heard about the possibility of any therapy. This point is further discussed under "Geographical distribution".

Numerical distribution

During the period 1960–1969, a total of 2 066 cases of otosclerosis were seen in Norway (Fig. 4). This represents 0.56 per thousand of the population. The present study, however, only comprises a 10-year period. Assuming that otosclerosis for the major part occurs within a 50-year period of life, on the average otosclerosis in Norway occurs in 0.3 per cent of the population. It is hard to find comparable figures from other countries. Shambaugh (1949) states that otosclerosis possibly affects 0.5–1 per cent of the white population, but adds that no authors give any exact statistics of the incidence. However, Morrison & Bundey (1967) reported a major genetic and clinical study undertaken in East London during the years 1961–1964. Among a population of 248 591, 76_ patients were discovered with otosclerosis, from which the prevalence in East London was calculated to be 0.3 per cent, or the same as in Norway.

Sex distribution

In this study the proportion of women to men is 3 : 2. As mentioned before, this point has

Information on these three cases is based on personal communication between the author and the surgeons involved.

which corresponds to 21 per cent of that department s cases 180 from Bergen which is 30 per cent of their cases and 105 from other clinics In all 168 fenestrations were performed or 1 8 per cent of the total material Fig 15 shows the combinations of operations applied seen on a national scale Like Fig 12 this figure must also be read crosswise

Special circumstances

Special circumstances are usually noted among the routine anamnestic information in the records These data are shown in Fig 16 where the first column refers to the use of hearing aids In all 759 of the 2066 patients were or had been using hearing aids which represents 37 per cent The distribution of those employing hearing aids varied somewhat when seen in proportion to the number of patients in the various departments In Rikshospitalet 38 per cent were using hearing aids in Ullevål 28 per cent in Bergen 41 per cent in Namsos 39 per cent in Bodo 31 per cent and in Tromso 19 per cent The second column shows that in all 166 or 8 per cent of the patients had been noise expositioned and the third column indicates that 84 or 4 per cent had been exposed to blows/explosions or head traumas Of particular interest is the *question of otosclerosis and pregnancy* The common concept is that the symptoms are either noticed for the first time during pregnancy or they are aggravated 107 of the 1341 women in the material representing 8 per cent gave such information 92 or 4 5 per cent of the patients also had ear trouble of another origin such as chronic otitis or secretory *otitis*

Fig 16

obvious that a citizen living in noisy surroundings and compelled to discriminate quickly between different noises has a greater need for good hearing than has a farmer or a lumberjack. The urban population also has a far greater need for speech communication

Thus the varying impulse to contact a doctor is partly dependent upon the environment. There are certainly many cases in the areas mentioned which would show up if we had a better service better information or more E N T clinics It must be concluded that a large part of Norway lies on a poor social level in these respects and in some of our counties the distance to surgical E N T service is far too long

As the majority of otosclerous patients belong to the urban population one might also take into consideration whether differences exist in the age or sex distribution between rural and urban districts However our Statistical Central Bureau has provided the information that during the years in question this factor played no role

Age distribution

The present statistics show that 57 7 per cent of the patients suffering from otosclerosis in Norway are more than 50 years of age while only 1.5 per cent are below 20 years This is not quite in agreement with the findings of Larsson (1960) who found the majority of cases being between 11 and 45 years of age or Morrison (1967) who stated that 91 per cent of his cases were between 15 and 45 years Only 4 per cent in his material were above 45 years of age Thus weighting towards higher age in Norway must be due to several reasons In the first place the accumulation of cases during the preceding decades must be important. As 23 per cent of the patients were above 60 years of age this implies that Norwegian otologists were late in applying modern operative methods The method was first developed in the greater clinics abroad then applied in the university clinics of Norway and from there brought to outlying clinics In Norway an E N T surgeon in private practice cannot operate in the county clinic unless his chief position is within the hospital Thus some time had passed before the new methods applied abroad were common in our peripheral clinics

Secondly part of the reason may be that our information to the public has been neglected As always this point is a crux medicorum which the doctor postpones if possible and the patients get their information too late It does not suffice to inform only those patients applying for a consultation some public information must also be given in order to bring the knowledge of the usually excellent results of these operations to all possible patients

Inheritance

As related earlier the question of a familial occurrence of loss of hearing is described by referring to the information in the patients records The cases where the loss of hearing in parents or near relatives started in the years above middle age were not considered only those where it started before 45 years of age and where causes for the hearing defects other than the suspicion of otosclerosis were not obvious Such information of course depends upon both the scrutiny of the examining intern and of the patient s own judgement of his relatives hearing Both circumstances call for certain reservations as to the exactness of the obtained information However the statistics seem very convincing 1 049 patients or 50.8 per cent of the material reported loss of hearing among members of their family (Fig 10) Loss of hearing among parents were dominating this was reported by 515 patients but none of these had noted it in both parents The next obvious point was that several patients reported hearing loss in several relatives (Fig 1?) This figure shows in the first place that the inheritance of otosclerosis as also reported by Davis and Silverman (1970) must be due to a gene which may be present in

been much discussed in the literature Shambaugh Jr (1949) also indicated the ratio 3 2 whilst Larsson (1960) and Ballantyne (1960) found it to be 2 1 Altmann (1967) indicated 7 6 Sakai (1971) 1 1 Morrison (1971) also finds the proportion to be 1 1 when including the out patients including only those who received a thorough examination when admitted to a hospital He explains discrepancies by the fact that women often notice their otosclerosis during pregnancy and then demand an examination whereas men are used to working in a more noisy environment where people are talking loud which implies that they do not so easily discover their otosclerosis Thus the later papers show that the proportion of women to men approaches 1 1 when a more thorough examination is performed It is reasonable to believe that this argumentation also might be valid for Norway According to the present statistics there are only one third more women than men not twice as many as most textbooks maintain

Case distribution

As might be expected the majority of cases are found during the years 1964–1967 During these years surgical techniques and microscopes were improved fenestration was replaced by stapediolysis whereupon the scientific literature on the subject grew enormously hence also the popular articles Following this information more patients became aware of the possibility of surgical treatment and hence the number of known cases greatly increased during that period

Geographical distribution

The accumulation of patients in the densely populated areas shown in the two maps of Southern and Northern Norway (Figs 6 7 and Fig 4) must have an explanation There is no proof for the assumption that otosclerosis should be more frequent in denser population and moreover this investigation shows a great difference in the number of patients even between the densely populated areas e g Oslo where there are 7 6 patients per 10000 inhabitants compared to Bergen where there are 13 24 per 10000

Several factors serve to elucidate this discrepancy In Bergen otosclerosis operations were not performed before 1961 At that time periodicals and scientific communications (e g Gundersen 1973) had informed the population about the disease and the operative possibilities As the other clinics performing these operations mainly Rikshospitalet already had long waiting lists the patients had small chances of receiving treatment elsewhere and an accumulation of patients wanting examination and operation occurred So when the opportunity came there was an onrush of patients seeking admissions In addition one must also take into consideration the priorities set by a certain clinic the number of beds in the clinic and the ability and interests of the physicians as factors deciding which cases may be admitted If for instance a clinic like Rikshospitalet has a great press from cases needing cancer surgery otosclerosis patients may receive low priority

The considerations mentioned above explain some of the differences between the densely populated areas differences which are apt to be equalized as the years go by However it is not explained why the incidence is so low in the northern areas Troms (0 32 per cent) and Finnmark (0 22 per cent) and in the mountainous areas in the middle of Norway Hedmark (0 36 per cent) Oppland (0 28 per cent) Aust Agder and Telemark (both 0 26 per cent) If the frequency of cases in Bergen (1 32 per cent) reflects the true incidence there should be from 4 to 6 time as many cases also in these areas

Several factors may serve to explain this uneven distribution In the first place consultations become rarer the longer the distance to the doctor Moreover otosclerosis is a disease one may cope with if the need for communication is moderate as in rural districts It is

obvious that a citizen living in noisy surroundings and compelled to discriminate quickly between different noises has a greater need for good hearing than has a farmer or a lumberjack. The urban population also has a far greater need for speech communication.

Thus the varying impulse to contact a doctor is partly dependent upon the environment. There are certainly many cases in the areas mentioned which would show up if we had a better service, better information or more E.N.T. clinics. It must be concluded that a large part of Norway lies on a poor social level in these respects, and in some of our counties the distance to surgical E.N.T. service is far too long.

As the majority of otosclerosis patients belong to the urban population, one might also take into consideration whether differences exist in the age or sex distribution between rural and urban districts. However, our Statistical Central Bureau has provided the information that during the years in question this factor played no role.

Age distribution

The present statistics show that 57.7 per cent of the patients suffering from otosclerosis in Norway are more than 50 years of age, while only 1.5 per cent are below 20 years. This is not quite in agreement with the findings of Larsson (1960), who found the majority of cases being between 31 and 45 years of age, or Morrison (1967) who stated that 91 per cent of his cases were between 15 and 45 years. Only 4 per cent in his material were above 45 years of age. This weighting towards higher age in Norway must be due to several reasons. In the first place, the accumulation of cases during the preceding decades must be important. As 3 per cent of the patients were above 60 years of age, this implies that Norwegian otologists were late in applying modern operative methods. The method was first developed in the greater clinics abroad, then applied in the university clinics of Norway, and from there brought to outlying clinics. In Norway an E.N.T. surgeon in private practice cannot operate in the county clinic unless his chief position is within the hospital. Thus some time had passed before the new methods applied abroad were common in our peripheral clinics.

Secondly, part of the reason may be that our information to the public has been neglected. As always, this point is a crux medicorum which the doctor postpones if possible, and the patients get their information too late. It does not suffice to inform only those patients applying for a consultation, some public information must also be given in order to bring the knowledge of the usually excellent results of these operations to all possible patients.

Inheritance

As related earlier, the question of a familial occurrence of loss of hearing is described by referring to the information in the patients' records. The cases where the loss of hearing in parents or near relatives started in the years above middle age were not considered, only those where it started before 45 years of age and where causes for the hearing defects other than the suspicion of otosclerosis were not obvious. Such information of course depends upon both the scrutiny of the examining intern and of the patient's own judgement of his relatives' hearing. Both circumstances call for certain reservations as to the exactness of the obtained information. However, the statistics seem very convincing: 1 049 patients or 50.8 per cent of the material reported loss of hearing among members of their family (Fig. 10). Loss of hearing among parents were dominating, this was reported by 515 patients, but none of these had noted it in both parents. The next obvious point was that several patients reported hearing loss in several relatives (Fig. 12). This figure shows in the first place that the inheritance of otosclerosis as also reported by Davis and Silverman (1970), must be due to a gene, which may be present in

one generation skip the next and then recur It is not always directly inherited and it may be present in several branches of a family A total of 190 patients reported hearing loss only in the grandparents or more remote relatives In addition this investigation shows that the inheritance is more obvious in Norway than in countries where otosclerosis is not so common Sakai (1971) found positive familial anamnestic information of a progressive hearing loss in only 20 per cent of his cases However to obtain decisive data for a pure genetic investigation the hearing level of relatives would have to be measured On the other hand a hearing loss reported among relatives in more than 50 per cent of the cases is a significant finding Also other data derived from the questionnaire showing 12 5 per cent of the cases reporting hearing loss among their parents and 1 4 per cent among their grandparents is a statistically significant overrepresentation in the families of otosclerosis patients compared to the normal population The result holds true despite faltering statements from the patients and the possibility that some of the reported hearing defects may be due to other diseases like presbyacusis or noise injuries

The number of hearing defects reported among siblings varies according to their total numbers which is not known If the number of siblings vary from one to four the percentage of reported hearing defects vary from 13 ? to 1 9 per cent which are also quite convincing numbers compared to the prevalence of otosclerosis in the whole population −0 3 per cent Since only family members who suffered from hearing defects before the age of 45 were considered the conclusion must be that hearing defects among the parents grandparents or siblings of otosclerotics are far more common than otosclerosis in the whole population

Operations

Of the 2066 cases 1981 were operated on only 85 were not Of these 85 54 were from Rikshospitalet while in Bergen all patients had surgery This is probably primarily due to the fact that in Bergen the patients have to a higher extent been thoroughly examined as out patients and are ready for operation before they are hospitalized whereas Rikshospitalet receives patients from all over the country and the eventual indications for operation must be evaluated after hospitalization Moreover it may also be explained by the surgeons attitude as appears from most data Some are optimistic regarding the advantages of an operation others are more reluctant

It is not the purpose of this study to indicate what surgical methods were actually applied but it appeared from the study of the records that fenestrations are definitively abandoned and so are stapediolyses while stapedectomy is the dominating procedure including all the various prostheses described in the literature It is seen in Fig 15 that most patients have had surgery once on one side (1 ?85) Of course most patients manage if hearing well in one ear but the fact that only 350 had bilateral operations suggests that our otologists possibly because of the risk involved in surgery are reluctant to perform it bilaterally It also appears in Fig 15 that 111 patients have been operated on more than once on the same side a procedure including less risk than bilateral operations

SPECIAL CIRCUMSTANCES

Under special circumstances criteria relevant to otosclerotic disease were recorded

Hearing aids

In this group both those using hearing aids before and after surgery are included They are not divided into separate groups because this would have implied discussing the results of the operations which was not the intention Consequently the data are mostly of social interest. The fact that 3? per cent of the patients had adopted themselves to the use of hearing aids proves that the possibility of acquiring these in Norway is now rather good This is no doubt due to our social security benefits Furthermore the numbers of hearing aid users both before and after surgery can be taken as evidence for the value of these devices Hence the otologist must consider for each patient not only the relevance of surgery but the possible benefit of applying a hearing aid

Noise

Here those patients are included who stated to have been exposed to noise to such an extent that it might have influenced their hearing These were 166 or 8 4 per cent which seems to be a small figure indicating that noise represents no major problem in this connection These patients do not perceive the noise as easily as those with normal hearing However according to the present knowledge of the damage in the auditory system caused by noise it is obvious that a postoperative noise exposition will be particularly disabling to such patients Therefore as a general rule they are advised to avoid working in a noisy environment

Blows, explosions and head traumas

84 patients or 4 per cent, had been exposed to these traumas a considerably lower figure than expected There is no reason to expect traumas to have any etiological significance concerning otosclerosis but the greater part of this material consists of patients more than 50 years of age who have lived through the war in Norway which must have afflicted a sensorineural hearing loss on some However the number of patients affected by such conditions is not so large as to require a more exhaustive discussion nor does it interfere with the other statistical data.

Pregnancy as a precipitating factor

Morrison (1971) stated that 12 per cent discovered the disease during pregnancy and another 4? per cent had an aggravation of the hearing loss during pregnancy In Handbuch der Ohrenheilkunde (Marx 1938) the hearing loss in otosclerosis is said to increase with the number of pregnancies This occurs to 30 per cent at the first to 60 per cent at the second and to 80 per cent if there are three pregnancies or more This is in Scandinavia as well regarded as an axiom and is stated in all text books Still there is a long step from the 8.3 per cent Norwegians who stated that they discovered initial or worsening hearing loss during pregnancy to the 4 per cent referred by Morrison or the 30 per cent referred by Marx Even if one takes into consideration the imperfect records where the difference between the pregnancies was not always pointed out the 8.3 per cent cannot be particularly wrong. The conception that the hearing loss in otosclerosis increases during pregnancy is so well implanted into the minds of E N T interns that the point was seldom omitted during the elaboration of the records Possibly the increasing considerations for the womens condition during pregnancy and the improved living conditions play a role so that several features during pregnancy are improved including the hearing deficiency Scientists are now discussing whether the symptoms actually do tend to start or increase as a result of preg

nancy One should remember that the age where the greatest incidence of this disease occurs coincides with the age of pregnancies and the earliest osseous changes start long before the symptoms are discovered In the present study 1341 of the 2066 patients were women 107 or only 8 3 per cent stated that they noticed the disease or it became worse during pregnancy This low figure suggests that the deep-rooted idea of worsening during pregnancy may have to be revised

Other diseases

92 patients or 4.5 per cent had additional ear diseases There is no statistics showing the number of acute chronical or secretory otitis but the figure 4.5 per cent agrees with the number of hard of hearing persons in a normal population (Hall 1956 Ballantyne 1960 Davis & Silverman 1970) It seems reasonable to assume that the predisposition for otosclerosis is not related to any general tendency toward ear diseases

Summary and Conclusions

The records of all patients suffering from otosclerosis from the six clinics of Norway which offered surgical treatment of this disease were studied for the period 1960–1969

During the decade 1960–1969 there were in Norway 2066 patients admitted to these clinics which means that at any time there is approximately 0 3 per cent of the population suffering from this disease

The proportion of women to men was 3 2 which does not confirm the previous assumptions that otosclerosis is twice as frequent in women as in men

There was a higher frequency of patients in the densely populated areas which is quite reasonable in view of the better opportunity to treatment There were about twice as many cases per inhabitant in Western Norway i e in the city and surrounding districts of Bergen as in Oslo which is probably due to the fact that in the former district one did not start otosclerosis surgery until 1961 and this led to an accumulation of patients waiting for admittance

These conditions are also reflected in the age distribution In previous studies only 4 per cent were over age 45 whereas in Norway 58 per cent were above age 50

51 per cent of the patients stated that some of their closer relatives suffered from a loss of hearing at an early age The present material confirms the findings of previous authors that hearing losses occur much more frequently in the patients parents grandparents and siblings than among the rest of the population

96 per cent of the patients were operated upon 70 per cent unilaterally 22 per cent bilaterally The method of choice was the stapedectomy with varying types of prostheses

37 per cent of the patients were using or had been using hearing aids

Only 8 per cent of the patients complained that noise aggravated their disease

Only 8 per cent of the women stated that the symptoms started or worsened during pregnancy This low figure shed doubt on the assumption that pregnancies tend to worsen otosclerosis

Otosclerosis also occurs in the Lapp population in Norway We have evidence that in three members of this race otosclerosis was diagnosed and operation performed

Résumé et Conclusions

Les documents sur l otosclérose provenant des six cliniques norvégiennes opérant cette maladie ont été analysés pour la période 1960-1969

A cause de difficultés practiques nous n a ons pas obtenu comme attendu, un aperçu pour la population laponne mais il a est montré que jusqu à maintenant trois Lapons ont été opérés pour cette maladie L otosclérose existe donc aussi chez les Lapons

Dans la période 1960-1969 il a été enregistré en Norvège 2066 patients souffrant d'otosclérose Ce qui signifie qu en moyenne 0,3 pour cent de la population souffre de cette maladie.

La proportion femme homme était de 3 2 ce qui ne confirme pas tout à fait les précédentes suppositions que l otosclérose est deux fois plus répandue chez les femmes que chez les hommes

Il y avait une majorité de patients provenant de régions fortement peuplés ce qui est naturel quand on considère que l accès aux traitements est plus aisé Il y avait environ deux fois plus de cas par habitant sur la côte ouest aux environs de Bergen qu à Oslo ce qui probablement est dû au fait qu on a commencé à opérer l otosclérose à Bergen qu à partir de 1961 Il y avait alors un grand nombre de patients qui avait attendre un traitement

On retrouve la même situation en ce qui concerne la répartition d après l âge Précédentes études ont montré que seulement 4 pour cent avait plus de 45 ans tandis qu en Norvège 58 pour cent des patients avaient plus de 50 ans

51 pour cent des patients ont indiqués une réduction de l ouïe en relative bas âge chez les parents

Le matériel rassemble confirme ce qui a été trouvé dans de précédentes recherches La réduction d ouïe chez les parents des patients souffrant d otosclérose est beaucoup plus fréquente que l otosclérose chez le reste de la population

96 pour cent de patients ont été opérés 70 pour cent de ceux-ci ont été opérés une fois d un côté 22 pour cent ont été opérés des deux côtés La méthode d opération était la stapedectomie avec de différents types de protèse

37 pour cent des patients utilisaient ou avaient utilisé un appareil auditif

Seulement 8 pour cent des patients se plaignaient que le bruit semblait avoir aggravé leur cas

Seulement 8 pour cent de femmes ont indiqués que les symptômes avaient commencé ou s étaient aggravés durant la grossesse ce qui est une si petite proportion qu on peut douter de la supposition que la grossesse aggrave l otosclérose

The author is indebted to the head of the Otolaryngological Department at Rikshospitalet Oslo Professor P Berdal who suggested to me the subject of the present investigation

Sincere thanks are also due to the heads of the other otolaryngological clinics who all so willingly let me examine their records Professor T Leegaard Professor E Steen Dr H Fabritius Dr A Gulsvik and to the head of the Institute of Social Medicine University of Oslo Professor P Sandby for valuable advice in interpreting the results

The author also wishes to thank Miss S Hall and Mr A Ferber for the statistical ana-

nancy One should remember that the age where the greatest incidence of this disease occurs coincides with the age of pregnancies and the earliest osseous changes start long before the symptoms are discovered In the present study 1341 of the 2066 patients were women 107 or only 8 3 per cent stated that they noticed the disease or it became worse during pregnancy This low figure suggests that the deep-rooted idea of worsening during pregnancy may have to be revised

Other diseases

92 patients or 4.5 per cent had additional ear diseases There is no statistics showing the number of acute chronical or secretory otitis but the figure 4 5 per cent agrees with the number of hard of hearing persons in a normal population (Hall 1956 Ballantyne 1960 Davis & Silverman 1970) It seems reasonable to assume that the predisposition for otosclerosis is not related to any general tendency toward ear diseases

Summary and Conclusions

The records of all patients suffering from otosclerosis from the six clinics of Norway which offered surgical treatment of this disease were studied for the period 1960–1969

During the decade 1960–1969 there were in Norway 2066 patients admitted to these clinics which means that at any time there is approximately 0 3 per cent of the population suffering from this disease

The proportion of women to men was 3 2 which does not confirm the previous assumptions that otosclerosis is twice as frequent in women as in men

There was a higher frequency of patients in the densely populated areas which is quite reasonable in view of the better opportunity to treatment There were about twice as many cases per inhabitant in Western Norway i e in the city and surrounding districts of Bergen as in Oslo which is probably due to the fact that in the former district one did not start otosclerosis surgery until 1961 and this led to an accumulation of patients waiting for admittance

These conditions are also reflected in the age distribution In previous studies only 4 per cent were over age 45 whereas in Norway 58 per cent were above age 50

51 per cent of the patients stated that some of their closer relatives suffered from a loss of hearing at an early age The present material confirms the findings of previous authors that hearing losses occur much more frequently in the patients parents grandparents and siblings than among the rest of the population

96 per cent of the patients were operated upon 70 per cent unilaterally 22 per cent bilaterally The method of choice was the stapedectomy with varying types of prostheses

37 per cent of the patients were using or had been using hearing aids

Only 8 per cent of the patients complained that noise aggravated their disease

Only 8 per cent of the women stated that the symptoms started or worsened during pregnancy This low figure sheds doubt on the assumption that pregnancy tends to worsen otosclerosis

Otosclerosis also occurs in the Lapp population in Norway We have evidence that in three members of this race otosclerosis was diagnosed and operations performed

lysis and the programming of the codes for the computer Mrs B Branil for technical assistance and photography Mrs K Steinsheim Haga for the typing of the manuscript and Mrs C Rydell for editorial assistance

The investigation was carried out with the help of grants from the Anders Jahres fond til vitenskapens fremme

Bleomycin Lundbeck

A new oncolytic agent

Bleomycin is a new oncolytic agent which has been shown to have
No toxic effect on the bone marrow
No immunosuppressive action

Bleomycin may be useful in the management of

1 Squamous cell carcinoma affecting the mouth nasopharynx and paranasal sinuses larynx oesophagus external genitalia or skin The best response has been obtained in well differentiated tumours

2 Hodgkin s disease and other lymphomas including mycosis fungoides

3 Testicular teratoma

There have been no reports of cross resistance with other currently used oncolytic agents

Dose 15 mg–30 mg intramuscularly or intravenously to a total dose of up to 300 mg depending on factors including the condition to be treated and the age of the patient.

Adverse reactions Side effects which may occur include fever anorexia, tiredness, nausea and the development of lesions of the skin or oral mucosa. Interstitial pneumonia may occur during, or occasionally after a course of treatment. This condition may on occasions, develop into fatal pulmonary fibrosis but such an occurrence is rare on recommended doses. Patients undergoing treatment should have chest X-rays taken weekly.

Contraindications Pregnancy Patients with acute lung infection should not be treated with Bleomycin before the infection is under control.

Precautions Contact with the skin should be avoided.

INTRODUCTION

Many tests have been developed during the last decades for the differential diagnosis of sensori-neural hearing loss. Recruitment measurements have particularly attracted the audiologist's interest because loudness recruitment has been found to be associated with the lesions in the organ of Corti. Dix, Hallpike & Hood (1948) demonstrated positive recruitment particularly in Ménière's disease and showed further that it does not occur in connection with lesions of the VIII cerebral nerve or higher acoustic centres. Similar results have been reported by Eby & Williams (1951), Lundborg (1952), Kristensen & Jepsen (1952), and Dix & Hallpike (1958). However, some authors have also found mostly partial but sometimes even complete loudness recruitment also in conductive hearing loss (Palva & Ojala 1955, Anderson & Barr 1968, Kärjä 1970). This phenomenon is considered mechanical in nature and not due to receptor organ lesions.

Tests for loudness recruitment can be divided into the direct and the indirect. The latter attempt to measure the rate of loudness increase: they include particularly the intensity difference limen tests (Lüscher & Zwislocki 1948, 1949, Denes & Naunton 1950, Hirsh et al. 1952) and, in borderline cases, automatic threshold audiometry (Reger & Kos 1952, T. Palva 1957). For testing minor excursions in cases of recruiting deafness, the last mentioned is the only indirect test to remain in widespread use.

Direct tests of loudness recruitment can be performed on a great majority of patients and obviously are the procedure of choice in its detection and measurement. In these supra-threshold tests, the increase in loudness at a certain frequency in the affected ear is directly compared with that in the normal ear at the same frequency (Fowler 1928, 1936) or at two different frequencies (Reger 1936), one tested with normal and the other with impaired hearing.

In Fowler's Alternate Binaural Loudness Balance (ABLB) test, it is presupposed that one ear has normal or nearly normal hearing. The tone can be switched over from one ear to the other either manually or automatically. For physiological reasons, the rise-decay time of the tone must be short enough (50 msec) and identical for both ears. To avoid adaptation and auditory fatigue, the sound should be short, 0.3—0.5 sec (Lidén 1962) but not shorter than 200 msec (Munson 1947, Garner 1947). In some studies the comparison has been carried out by measuring the loudness balance of the tones simultaneously in both ears, but Hood (1950) showed that the results were not always reliable even in clear cases of recruitment. Indeed, in these cases interaural localization is substituted for loudness balance proper and the mechanisms are different.

The ABLB test can be carried out at any frequency and Fowler presented the results of the loudness balance either in a system of coordinates as the function of the reference and test tone, or by a columnar scale graph.

INTRODUCTION

Many tests have been developed during the last decades for the differential diagnosis of sensori neural bearing loss. Recruitment measurements have particularly attracted the audiologist s interest because loudness recruitment has been found to be associated with the lesions in the organ of Corti. Dix, Hallpike & Hood (1948) demonstrated positive recruitment particularly in Ménière s disease and showed further that it does not occur in connection with lesions of the VIII cerebral nerve or higher acoustic centres. Similar results have been reported by Eby & Williams (1951) Lundborg (1952) Kristensen & Jepsen (1952) and Dix & Hallpike (1958) However some authors have also found mostly partial but sometimes even complete loudness recruitment also in conductive hearing loss (Palva & Ojala 1955 Anderson & Barr 1968 Kärjä 1970) This phenomenon is considered mecha nical in nature and not due to receptor organ lesions.

Tests for loudness recruitment can be divided into the direct and the indirect. The latter attempt to measure the rate of loudness increase: they include particularly the intensity difference limen tests (Lüscher & Zwislocki 1948, 1949 Denes & Naunton 1950 Hirsh et al 1952) and, in borderline cases automatic threshold audiometry (Reger & Kos 1952, T Palva 1957) For testing minor excursions in cases of recruiting deafness, the last mentioned is the only indirect test to remain in widespread use

Direct tests of loudness recruitment can be performed on a great majority of patients and obviously are the procedure of choice in its detection and measurement. In these supra threshold tests the increase in loudness at a certain frequency in the affected ear is directly compared with that in the normal ear at the same frequency (Fowler 1928 1936) or at two different frequencies (Reger 1936) one tested with normal and the other with impaired hearing

In Fowler's Alternate Binaural Loudness Ba lance (ABLB) test it is presupposed that one ear has normal or nerly normal hearing The tone can be switched over from one ear to the other either manually or automatically For physio logical reasons, the rise-decay time of the tone must be short enough (50 msec) and identical for both ears To avoid adaptation and auditory fatigue the sound should be short, 0.3—0.5 sec (Lidén 1962) but not shorter than 200 msec (Munson 1947 Garner 1947) In some studies the comparison has been carried out by measuring the loudness balance of the tones simultaneously in both ears, but Hood (1950) showed that the results were not always reliable even in clear cases of recruitment. Indeed in these cases interaural localization is substituted for loudness balance proper and the mechanisms are different.

The ABLB test can be carried out at any frequency and Fowler presented the results of the loudness balance either in a system of coordinates as the function of the reference and test tone or by a columnar scale graph.

INTRODUCTION

Many tests have been developed during the last decades for the differential diagnosis of sensori neural hearing loss. Recruitment measurements have particularly attracted the audiologist's interest because loudness recruitment has been found to be associated with the lesions in the organ of Corti. Dix, Hallpike & Hood (1948) demonstrated positive recruitment particularly in Ménière's disease and showed further that it does not occur in connection with lesions of the VIII cerebral nerve or higher acoustic centres. Similar results have been reported by Eby & Williams (1951) Lundborg (1952) Kristensen & Jepsen (1952) and Dix & Hallpike (1958) However some authors have also found mostly partial but sometimes even complete loudness recruitment also in conductive hearing loss (Palva & Ojala 1955 Anderson & Barr 1968 Kärjä 1970) This phenomenon is considered mechanical in nature and not due to receptor organ lesions.

Tests for loudness recruitment can be divided into the direct and the indirect. The latter attempt to measure the rate of loudness increase they include particularly the intensity difference limen tests (Lüscher & Zwislocki 1948, 1949 Denes & Naunton 1950, Hirsh et al. 1952) and, in borderline cases, automatic threshold audiometry (Reger & Kos 1952, T Palva 1957) For testing minor excursions in cases of recruiting deafness, the last mentioned is the only indirect test to remain in widespread use.

Direct tests of loudness recruitment can be performed on a great majority of patients and obviously are the procedure of choice in its detection and measurement. In these supra-threshold tests, the increase in loudness at a certain frequency in the affected ear is directly compared with that in the normal ear at the same frequency (Fowler 1928, 1936) or at two different frequencies (Reger 1936) one tested with normal and the other with impaired hearing

In Fowler's Alternate Binaural Loudness Balance (ABLB) test, it is presupposed that one ear has normal or nearly normal hearing The tone can be switched over from one ear to the other either manually or automatically For physiological reasons the rise-decay time of the tone must be short enough (50 msec) and identical for both ears. To avoid adaptation and auditory fatigue, the sound should be short, 0.3—0.5 sec (Lidén 1962) but not shorter than 200 msec (Munson 1947 Garner 1947) In some studies the comparison has been carried out by measuring the loudness balance of the tones simultaneously in both ears, but Hood (1950) showed that the results were not always reliable even in clear cases of recruitment. Indeed in these cases interaural localization is substituted for loudness balance proper and the mechanisms are different.

The ABLB test can be carried out at any frequency and Fowler presented the results of the loudness balance either in a system of coordinates as the function of the reference and test tone, or by a columnar scale graph

Reger's monaural loudness balance test is applicable to cases in which the hearing defect is bilateral but of different degree at different frequencies. Comparison is carried out using two frequencies monaurally at one or several supra-threshold levels. The reference tone usually chosen is 1000 Hz but if it is impaired by the same degree as the test tone a generally lower reference tone is chosen. Since the frequencies with a normal threshold can be either in the same or contralateral ear as the test tone the measurement can in principle be either monaural or binaural. Reger suggested 30 dB as the necessary threshold difference between the tested frequencies since loudness comparison is more difficult in the monaural than the binaural test.

Loudness correlation of different frequencies, the phon contours, were published by Kingsbury (1927) and by Fletcher & Munson (1933) and were further amplified by Churcher & King (1937). These experiments employed the manual testing techniques using the method of adjustment or the method of constant stimuli both with earphones and in the free field. In normally hearing test subjects with 1000 Hz as the reference tone a phenomenon similar to loudness recruitment appeared at low and high frequencies. This has an immediate implication on the Reger's test which in effect is based on normal equal loudness level contours.

In recent years self recording Békésy type automatic audiometry has become widespread for various audiologic tests. In addition to its versatile use for both threshold and supra-threshold tests the recording procedure itself makes it possible to employ the method of adjustment for the patient's responses. Using the method of limits or constant stimuli there is a certain interaction between the examiner and the test subject whereas self recording provides another type of response in which the examiner has no essential part. In this study one of the purposes has been to test how well the phon contours can be reproduced by the automatic recording technique in normally hearing persons. The task of making recordings of a loudness balance of two tones different both in frequency and intensity might prove very difficult if not impossible without guidance from the examiner. Furthermore the results if reliable and reproducible have a direct correlation to Reger's test at various frequencies. Stated in more detail this study aims by comparing the automatic testing techniques on a normal material to

- investigate whether automatic audiometry can be used for reliable loudness level comparison at various frequencies and to
- compare these results with the classical phon contour data.

Further the data will be used to

- find out how the size of the threshold excursions varies at various test combinations to
- find out whether the results obtained by monaural or binaural testing techniques are different to
- study how well frequencies that are far apart can be used for loudness matches and to
- transform the normal values of loudness comparison between various pure tones into a scale graph in order to obtain normal references for the Reger test with automatic audiometry.

EARLIER STUDIES ON EQUAL-LOUDNESS CONTOURS

The first extensive study of the intercorrelations of the loudness levels of pure tones was published by Kingsbury in 1927 He examined 22 subjects to whom the stimulus was given monaurally through a high-impedance ear-phone. The reference tone was 700 Hz with which 11 other frequencies, ranging from 60 to 4000 Hz, were compared. The highest intensity levels used were up to 90 T U (transmission units equal to dB) above the 700 Hz threshold. Comparisons were made at 10 dB intervals. The equipment consisted of two oscillators, one giving the reference tone and the other the test tone the intensity of which was manually adjusted by the subject himself The attenuator dial of the latter oscillator was covered by cardboard to prevent the test subject from seeing it Duration of the sound impulses used was not indicated.

Kingsbury concluded that if the amplitude of the various test frequencies was raised at equal steps the low tones increased in loudness much more rapidly than the high ones For frequencies above 700 Hz the rate of loudness level increase was found to be nearly uniform

Basic work on equal loudness levels at threshold was made by Sivian & White (1933) These measurements were carried out using tones ranging from 100 to 15000 Hz for monaural hearing and from 60 to 15000 Hz for binaural hearing on 13 observers. At 1000 Hz the minimum audible field corresponded to a pressure of 71 dB below 1 bar Another set of measurements were made concerning minimum audible pressures measured at the observer s ear drum The slightly different threshold values obtained were explained as being due to wave motion in the ear canal and and to diffraction caused by the head.

Fletcher and Munson published their classic study in 1933 using the sound stage and the technique of measuring field pressures as described by Sivian & White (1933) The voltage levels in the earphones were thus compared to those of loudspeakers giving equally loud tone sensations in a free field Their series comprised 11 test subjects using binaural earphones. Threshold measurements were made before and after the loudness level comparison using the same circuit. The constant stimulus method, under which the test subject simply stated which of the two tones was louder or softer was used for the comparison. The test tones consisted of ten frequencies within the range of 62 16000 Hz, and the reference tone was 1000 Hz, the test subjects sitting in a sound proof booth They first heard the test tone and 0.5 sec later the reference tone the two sounds lasting 1 sec each. This was followed by a pause of 1 sec and the same sequence was repeated The rise-decay time of the sound impulses was about 0 1 sec. Comparison levels extended from threshold values up to c 115 dB Fletcher and Munson discovered that their equal loudness contours were similar to those of Kingsbury between 100 and 2000 Hz, while differences in both directions were observed at lower and higher frequencies. The authors

EARLIER STUDIES ON EQUAL-LOUDNESS CONTOURS

The first extensive study of the intercorrelations of the loudness levels of pure tones was published by Kingsbury in 1927. He examined 22 subjects to whom the stimulus was given monaurally through a high-impedance ear phone. The reference tone was 700 Hz with which 11 other frequencies, ranging from 60 to 4000 Hz, were compared. The highest intensity levels used were up to 90 TU (transmission units equal to dB) above the 700 Hz threshold. Comparisons were made at 10 dB intervals. The equipment consisted of two oscillators, one giving the reference tone and the other the test tone the intensity of which was manually adjusted by the subject himself. The attenuator dial of the latter oscillator was covered by cardboard to prevent the test subject from seeing it. Duration of the sound impulses used was not indicated.

Kingsbury concluded that if the amplitude of the various test frequencies was raised at equal steps the low tones increased in loudness much more rapidly than the high ones. For frequencies above 700 Hz the rate of loudness level increase was found to be nearly uniform.

Basic work on equal-loudness levels at threshold was made by Sivian & White (1933). These measurements were carried out using tones ranging from 100 to 15000 Hz for monaural hearing and from 60 to 15000 Hz for binaural hearing on 13 observers. At 1000 Hz the minimum audible field corresponded to a pressure of 71 dB below 1 bar. Another set of measurements were made concerning minimum audible pressures measured at the observer's ear drum. The slightly different threshold values obtained were explained as being due to wave motion in the ear canal and and to diffraction caused by the head.

Fletcher and Munson published their classic study in 1933 using the sound stage and the technique of measuring field pressures as described by Sivian & White (1933). The voltage levels in the earphones were thus compared to those of loudspeakers giving equally loud tone sensations in a free field. Their series comprised 11 test subjects using binaural earphones. Threshold measurements were made before and after the loudness level comparison, using the same circuit. The constant stimulus method, under which the test subject simply stated which of the two tones was louder or softer was used for the comparison. The test tones consisted of ten frequencies within the range of 62-16000 Hz, and the reference tone was 1000 Hz, the test subjects sitting in a sound-proof booth. They first heard the test tone and 0.5 sec later the reference tone, the two sounds lasting 1 sec each. This was followed by a pause of 1 sec and the same sequence was repeated. The rise-decay time of the sound impulses was about 0.1 sec. Comparison levels extended from threshold values up to c. 115 dB. Fletcher and Munson discovered that their equal loudness contours were similar to those of Kingsbury between 100 and 2000 Hz, while differences in both directions were observed at lower and higher frequencies. The authors

suggested that these differences could possibly be due to a slight amount of noise during threshold measurements

Churcher & King (1937) carried out an extensive equal loudness determination with pure tones by means of free-field stimulation The study comprised 30 test subjects in groups of 10 who made the comparison with the constant stimulus method. The testing technique was manual in the same way as in the work by Fletcher & Munson (1933) The reference tone was 1000 Hz, and the test tones ranged from 54-9000 Hz. The duration of the sound impulses to be compared for the level of loudness was 2 sec and they were heard in rapid succession After a pause of 10 sec the sequence was repeated. The equal loudness level comparisons were made up to the level of 90 dB and the reference tone was increased by 10 dB steps

With free field stimulation a higher intensity than in the studies summarized above was required for the low frequency in order to equal the 1000 Hz loudness level at low stimulation levels. At the 80—90 phon level the divergence from Fletcher and Munson s curves was in the opposite direction The authors concluded that at frequencies higher than 1000 Hz the differences between receiver and free-field measurements are due to experimental errors while below 1000 Hz the differences are due to the two methods themselves

Zwicker & Feldkeller (1955) were the first to use automatic test technique in their study They had eight test subjects who listened to 0 6 sec long stimuli monaurally through an ear phone Loudness balances were made continuously according to the Békésy tracking technique The reference tone was 1000 Hz, and the test tones ranged from 50 to 20 000 Hz. Comparison was carried out in 10 dB steps up to the level of 90 dB at 1000 Hz. At first the test subject heard e.g a 500 Hz tone which changed continually by 1 dB/sec After 0 6 sec the 400 Hz tone disappeared and the subject heard the reference tone which remained constant in intensity After another 0 6 sec this was replaced by the test tone The test subject adjusted the test tone by switch control making it louder or softer In the course of the experiment the test tone changed continually so that the whole scale of frequencies was covered within 15 minutes. The measurements revealed that it was best to start the comparison from 1500 Hz and work downwards and again from 700 Hz upwards.

The equal loudness level contours of Zwicker & Feldtkeller (1955) were clearly more widely separated from each other at the low frequency — low stimulation levels than those of Fletcher & Munson (1933) Compared with the results by Churcher & King (1937) uniformity was poor at the high frequencies the self recorded values distinctly exceeding the free-field curves

Robinson & Dadson (1956) made an extensive study with pure tones using free field stimulation The constant stimulus method was used and the series consisted of nine test subjects. Frequencies ranging from 25 to 15000 Hz were used in the comparison and the sound pressure levels extended to 130 dB re 0 0002 dyn/cm² The most common reference tone was 1000 Hz, but comparisons were carried out with other pairs of frequencies also primarily to ensure the constancy of the equal loudness relations The duration of sound impulses varied between 1—3 sec depending on the frequencies compared Because of threshold deviation and the resulting disturbance in loudness comparison no comparisons were made at levels below 20 dB The studied frequencies were given alternatingly in the sequences AOBOAOB and BOAOBOAOB where A was the reference stimulus and B the test sound while O was the pause. The switching was complete at 0 15 sec The B sound varied over a wide scale of the sound pressure level so as to include with an adequate margin the transition levels of all observers A new feature noted in the results compared with those reported earlier was a dip in the contours between 400 and 500 Hz which was at its maximum on the middle levels

Recently Ross (1967) made a loudness level comparison study with three test subjects The stimuli were applied by an earphone through individually moulded ear inserts and sound pressures were measured at a distance of a few mm from the eardrum Thirteen frequencies

from 20 to 5000 Hz were compared. By pairs, each was once the reference tone and once the test tone. For threshold determination the duration of the sound impulse was 1.25 sec, and the same in the loudness comparisons. The reference and test tones were given consecutively without a pause. The test subject himself manually adjusted the intensity of the test tone. The comparison was carried out at 5 dB intervals beginning from values just above the threshold, and continued as high as the test subject could tolerate.

The equal-loudness-level contours obtained were similar to those reported from earlier studies but their rise was steeper at the low frequencies

suggested that these differences could possibly be due to a slight amount of noise during threshold measurements

Churcher & King (1937) carried out an extensive equal loudness determination with pure tones by means of free-field stimulation The study comprised 30 test subjects in groups of 10 who made the comparison with the constant stimulus method The testing technique was manual in the same way as in the work by Fletcher & Munson (1933) The reference tone was 1000 Hz, and the test tones ranged from 54 9000 Hz. The duration of the sound impulses to be compared for the level of loudness was 2 sec and they were heard in rapid succession After a pause of 10 sec the sequence was repeated The equal loudness level comparisons were made up to the level of 90 dB and the reference tone was increased by 10 dB steps

With free field stimulation a higher intensity than in the studies summarized above was required for the low frequency in order to equal the 1000 Hz loudness level at low stimulation levels. At the 80—90 phon level the divergence from Fletcher and Munson s curves was in the opposite direction The authors concluded that at frequencies higher than 1000 Hz the differences between receiver and free-field measurements are due to experimental errors while below 1000 Hz the differences are due to the two methods themselves.

Zwicker & Feldkeller (1955) were the first to use automatic test technique in their study They had eight test subjects who listened to 0 6 sec long stimuli monaurally through an ear phone Loudness balances were made conti nuously according to the Békésy tracking technique The reference tone was 1000 Hz, and the test tones ranged from 50 to 20 000 Hz Comparison was carried out in 10 dB steps up to the level of 90 dB at 1000 Hz At first the test subject heard e g a 500 Hz tone which changed continually by 1 dB/sec After 0 6 sec the 500 Hz tone disappeared and the subject heard the reference tone which remained constant in intensity After another 0 6 sec this was replaced by the test tone The test subject adjusted the test tone by switch control making it louder or softer In the course of the experiment the test tone changed continually so that the whole scale of frequencies was covered within 15 minutes The measurements revealed that it was best to start the comparison from 1500 Hz and work downwards and again from 700 Hz upwards.

The equal loudness level contours of Zwicker & Feldkeller (1955) were clearly more widely separated from each other at the low frequency — low stimulation levels than those of Fletcher & Munson (1933) Compared with the results by Churcher & King (1937) uniformity was poor at the high frequencies, the self recorded values distinctly exceeding the free-field curves

Robinson & Dadson (1956) made an extensive study with pure tones, using free-field stimulation The constant stimulus method was used and the series consisted of nine test subjects Frequencies ranging from 25 to 15000 Hz were used in the comparison and the sound pressure levels extended to 130 dB re 0 0002 dyn/cm² The most common reference tone was 1000 Hz but comparisons were carried out with other pairs of frequencies also primarily to ensure the constancy of the equal loudness relations The duration of sound impulses varied between 1—3 sec depending on the frequencies compared Because of threshold deviation and the resulting disturbance in loudness compa rison no comparisons were made at levels below 20 dB The studied frequencies were given alternatingly in the sequences AOBOAOB and BOAOBOAOB where A was the reference stimulus and B the test sound while O was the pause The switching was complete at 0 15 sec The B sound varied over a wide scale of the sound pressure level so as to include with an adequate margin the transition levels of all observers A new feature noted in the results compared with those reported earlier was a dip in the contours between 400 and 500 Hz, which was at its maximum on the middle levels

Recently Ross (1967) made a loudness level comparison study with three test subjects The stimuli were applied by an earphone through individually moulded ear inserts and sound pressures were measured at a distance of a few mm from the eardrum Thirteen frequencies

Both channels were led to the earphones via a switch box with which the examiner could direct either sound to the right or the left earphone. The head receivers were Beltone TDH 39 earphones mounted in MX41/AR cushions. The frequency response characteristics of the ear phones are shown in Fig. 2.

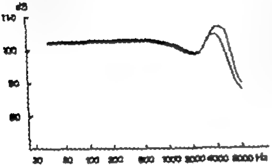

Fig. 2. The characteristics of earphones

The intensity of the test tone in channel 1 was controlled by the test subject with a press button switch he held in his hand. The rate of intensity was 2.1 dB/sec. All measurements were made using the SPL intensity scale of the Grason Stadler audiometer. The sound pressure levels in the earphones at 60 dB setting (Table 1) and with a fixed input of 0.1 V were calibrated using a 6 cc artificial ear and the Brüel—Kjaer measuring equipment. The 10 dB intensity steps of the audiometer intensity scale for both test and reference tone were checked for the whole frequency range tested up to the level of 115—120 dB and were found to be accurate.

Table 1. *The sound pressure levels in the earphones at 60 dB setting re 0.0002 dyn/cm*

Frequency	Right earphone	Left earphone
125	61	61
250	65	66
500	66	66.5
1000	66.5	67.5
2000	66	69
3000	65	68.5
4000	69	68
6000	68	66
8000	70	71.5

B Material and testing technique

The series examined consisted of 14 healthy test subjects who, with one exception, had never before attended an audiologic examination. Their ages ranged from 14 to [illegible], mean 24 years. The subjects selected had no known history of ear diseases and their eardrums were examined and found intact before hearing thresholds were measured. Every subject admitted to the final equal loudness measurement had, on the basis of the threshold measurements, normal hearing in both ears at the frequencies of 125, 250, 500, 1000, 2000, 3000, 4000, 6000 and 8000 Hz.

Hearing thresholds were measured only once since otherwise the test period would have become too long and the subjects might not have been able to concentrate on the tests of loudness level comparison.

By connecting the Philips generator to the electronic switch alternate stimulus input jack for the time of the measurements, the thresholds of the frequencies serving as reference could be registered with the automatic Békésy audiometer. The midpoint of the excursions was considered the threshold value.

Since it is known that the hearing threshold normally varies slightly depending on the subject's degree of fatigue and mental state, the threshold values for the equal loudness level measurements were selected by rounding off the mean values of the excursions to the nearest 5 dB.

Hearing thresholds were measured using continuous test tones which by-passed the interrupter. This was done because the interrupter produced a weak background noise in the earphones. The noise, however, was so soft that it could not be measured owing to the environmental noise of less than 25 dB in the examination room. The noise produced by the interruptions did not increase when comparison advanced to the higher soundpressure levels.

Before starting the threshold measurements the subjects were instructed to press the button in their hand when they heard the sound and to release the button when the sound disappeared.

EQUIPMENT MATERIAL AND TESTING TECHNIQUE

A Equipment

The study was carried out in the Audiological Laboratory of the Otolaryngological Department of Oulu University The equipment and the test subject were situated in separate sound proof rooms with a partition wall fitted with a triple-pane window The background noise measured (Precision Sound Level Meter Type 2203 Brüel and Kjaer Denmark) in the test room was less than 45 dB SPL re 0 0002 dyn/cm² Analysed by means of an octave filter (Type 1613 Brüel and Kjaer) the noise was found to consist of frequencies below 250 Hz In octave bands at the mean frequencies of 125 250 500 1000 2000 3000 4000 6000 and 8000 Hz, the attenuation rate being about 45—50 dB/octave the noise never exceeded 25 dB re 0 0002 dyn/cm²

The test arrangement is shown in Fig 1 The source of the test tones was a Grason Stadler Model E 800 Békésy audiometer the tones being led to channel 1 The reference tone was obtained from a Philips GM 238 sound generator and it was connected to the external input jack of the Grason Stadler audiometer and further to channel 2 The continuous tones from both sound sources were led to an interrupter which transformed them into 400 msec long pulses coming on alternatingly with a pause of 400 msec between them The rise and decay times were 30 msec each

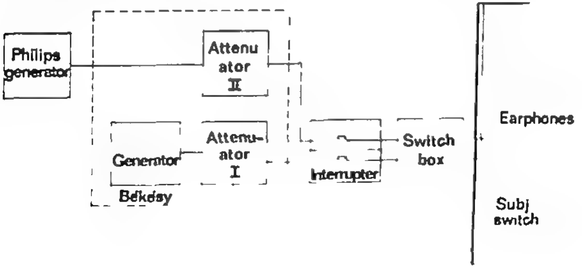

Fig 1 Arrangement of test apparatus

Both channels were led to the earphones via a switch box with which the examiner could direct either sound to the right or the left earphone. The head receivers were Beltone TDH 39 earphones mounted in MX41/AR cushions. The frequency response characteristics of the ear phones are shown in Fig. 2.

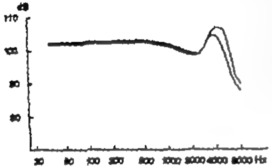

Fig. 2. The characteristics of earphones

The intensity of the test tone in channel I was controlled by the test subject with a press button switch he held in his hand. The rate of intensity was 2.1 dB/sec. All measurements were made using the SPL intensity scale of the Grason Stadler audiometer. The sound pressure levels in the earphones at 60 dB setting (Table 1) and with a fixed input of 0.1 V were calibrated using a 6 cc artificial ear and the Brüel—Kjaer measuring equipment. The 10 dB intensity steps of the audiometer intensity scale for both test and reference tone were checked for the whole frequency range tested up to the level of 115—120 dB and were found to be accurate.

2000	66	69
3000	65	68.5
4000	69	68
6000	68	64
8000	70	71.5

B Material and testing technique

The series examined consisted of 14 healthy test subjects who with one exception, had never before attended an audiologic examination. Their ages ranged from 14 to 29 mean 24 years. The subjects selected had no known history of ear diseases and their eardrums were examined and found intact before hearing thresholds were measured. Every subject admitted to the final equal loudness measurement had, on the basis of the threshold measurements, normal hearing in both ears at the frequencies of 125 250 500, 1000 2000 3000 4000, 6000 and 8000 Hz.

Hearing thresholds were measured only once since otherwise the test period would have become too long and the subjects might not have been able to concentrate on the tests of loudness level comparison.

By connecting the Philips generator to the electronic switch alternate stimulus input jack for the time of the measurements, the thresholds of the frequencies serving as reference could be registered with the automatic Békésy audiometer. The midpoint of the excursions was considered the threshold value.

Since it is known that the hearing threshold normally varies slightly depending on the subject's degree of fatigue and mental state, the threshold values for the equal loudness level measurements were selected by rounding off the mean values of the excursions to the nearest 5 dB.

Hearing thresholds were measured using continuous test tones which by-passed the interrupter. This was done because the interrupter produced a weak background noise in the earphones. The noise however was so soft that it could not be measured owing to the environmental noise of less than 25 dB in the examination room. The noise produced by the interruptions did not increase when comparison advanced to the higher soundpressure levels.

Before starting the threshold measurements the subjects were instructed to press the button in their hand when they heard the sound and to release the button when the sound disappeared.

Every frequency measured was registered for one minute The first equal loudness measurement was carried out 15 minutes after the threshold measurements or if threshold determination had taken an unusually long time or the test subject felt tired not until the following day

The frequency pairs compared were 4000—8000 4000—6000 3000—8000 3000—6000 3000—4000 2000—8000 2000—6000 2000—4000 2000—3000 1000—8000 1000—6000 1000—4000 1000—3000 1000—2000 1000—500 1000—250 1000—125 500—4000 500—2000 500—1000 250—4000 250—2000 250—1000 250—500 125—2000 125—1000 125—500 125—250 Hz. The first frequency of the pairs was the reference tone and the second the test tone

Comparison was carried out both mon and binaurally One half of the test subjects began with the monaural and the other with the binaural test In the monaural test both tones entered the right ear while in the binaural test the reference tone was always fed to the left ear and the test tone to the right ear Before the examination began the test subject was given a detailed description of his task during the test At first he heard only the reference tone but soon afterwards also the test tone The subject was requested to concentrate only on the loudness level of the frequencies compared and pay no regard to their different pitch When the test tone began to sound louder than the reference tone he pressed the control button and if the opposite was the case he could obtain a louder test tone by releasing it When the comparison began the author did not try to give the test tone "at the right level but let the test subject find the equal loudness level.

One minute per compared pair was allowed for the balancing The study was started at the 20 dB sensation level and continued on later days at 40 60 and 80 dB levels On the last day the comparison was carried out at almost the maximum intensity of the audiometer the reference tone reaching 60 dB at 125 Hz, 80 dB at 250 Hz 100 dB at 500 and 1000 Hz and 90 dB SL over 1000 Hz. If possible the comparisons were carried out at the various levels on consecutive days in order to avoid the test subjects catching diseases such as colds, coughs etc that might possibly affect their hearing during the examination On transition from a monaural to a binaural test a pause of 15 min was allowed In some cases e g owing to tiredness the latter half of the comparison had to be carried out the next day

TREATMENT OF DATA

Computer treatment of data was carried out using the BMD library programme O5R of UNIVAC 1108 (BMD = Biomedical Computer Programmes). The values of every pair of pure tones tested on the subject (e.g. 1000 Hz — 3000 Hz) were punched on cards, one pair per card (e.g. 030006). The equation selected for the curve to be calculated was the third-power polynomial $Y = A + BX + CX^2 + DX^3$ which in the trial run was found to illustrate best the equation of all the pairs of pure tones.

In the computer run the so-called parameter cards were added to the above value cards. The parameter cards indicate the number of the values (value cards) of the relevant test frequency pair, the power of the equation to be calculated (3) and a few other points associated with computer treatment. The card material obtained in this way was sent from the Oulu University Computer centre to UNIVAC in Helsinki.

The library programme O5R calculates from the material the mean values, standard deviations, the value of the constant (A), regression coefficients (B, C and D), the table for variance analysis, and the F value. The programme also gives the X and Y values and the polynomial values equalling the X values (the calculated values of Y) as well as the difference between the true and calculated values of Y. The X values are always reference frequency values and the Y values represent the test frequency.

Mathematical treatment

Programme O5R reads the X values (independent variable) and the Y values (dependent variable).

It is written

$Z_{ij} = X_i^j$ where $i = 1 \ldots n$ (number of values)

$j = 1 \ldots k$ (polynomial degree)

Product sums are calculated after the mean values have been subtracted from Z_{ij} and Y_i

$$W = \sum_{k=1}^{n} (Z_{ki} - \bar{Z}_i)(Z_{kj} - \bar{Z}_j)$$

$$t = \sum_{k=1}^{n} (Z_{ki} - \bar{Z}_i)(Y_k - \bar{Y})$$

$$S = \sum_{k=1}^{n} (Y_k - \bar{Y})$$

Regression coefficients are obtained by transposing the matrix W and multiplying it with t.

Value F shows how well the polynomial can be calculated from the material given. The table yields:

$F(1, 60) = 7.08$ $(P = 0.01)$ which means that the material is statistically reliable.

Every frequency measured was registered for one minute The first equal loudness measurement was carried out 15 minutes after the threshold measurements or II threshold determination had taken an unusually long time or the test subject felt tired not until the following day

The frequency pairs compared were 4000—8000 4000—6000 3000—8000 3000—6000 3000—4000 2000—8000 2000—6000 2000—4000 2000—3000 1000—8000 1000—6000 1000—4000 1000—3000 1000—2000 1000—500 1000—250 1000—125 500—4000 500—2000 500—1000 250—4000 250—2000 250—1000 250—500 125—2000 125—1000 125—500 125—250 Hz. The first frequency of the pairs was the reference tone and the second the test tone

Comparison was carried out both mon and binaurally One half of the test subjects began with the monaural and the other with the binaural test In the monaural test both tones entered the right ear while in the binaural test the reference tone was always fed to the left ear and the test tone to the right ear Before the examination began the test subject was given a detailed description of his task during the test At first he heard only the reference tone but soon afterwards also the test tone The subject was requested to concentrate only on the loudness level of the frequencies compared and pay no regard to their different pitch When the test tone began to sound louder than the reference tone he pressed the control button and if the opposite was the case he could obtain a louder test tone by releasing it When the comparison began the author did not try to give the test tone at the right level but let the test subject find the equal loudness level

One minute per compared pair was allowed for the balancing The study was started at the 20 dB sensation level and continued on later days at 40 60 and 80 dB levels On the last day the comparison was carried out at almost the maximum intensity of the audiometer the reference tone reaching 60 dB at 125 Hz, 80 dB at 250 Hz 100 dB at 500 and 1000 Hz and 90 dB SL over 1000 Hz If possible the comparisons were carried out at the various levels on consecutive days in order to avoid the test subjects catching diseases such as colds, coughs etc that might possibly affect their hearing during the examination On transition from a monaural to a binaural test a pause of 15 min was allowed In some cases e g owing to tiredness the latter half of the comparison had to be carried out the next day

TREATMENT OF DATA

Computer treatment of data was carried out using the BMD library programme OSR of UNIVAC 1108 (BMD = Biomedical Computer Programmes). The values of every pair of pure tones tested on the subject (e.g. 1000 Hz — 3000 Hz) were punched on cards, one pair per card (e.g. 030036). The equation selected for the curve to be calculated was the third-power polynomial. $Y = A + BX + CX^2 + DX^3$ which in the trial run was found to illustrate best the equation of all the pairs of pure tones.

In the computer run the so-called parameter cards were added to the above value cards. The parameter cards indicate the number of the values (value cards) of the relevant test frequency pair, the power of the equation to be calculated (3), and a few other points associated with computer treatment. The card material obtained in this way was sent from the Oulu University Computer centre to UNIVAC in Helsinki.

The library programme OSR calculates from the material the mean values, standard deviations, the value of the constant (A), regression coefficients (B, C and D), the table for variance analysis, and the F value. The programme also gives the X and Y values, and the polynomial values equalling the X values (the calculated values of Y), as well as the difference between the true and calculated values of Y. The X values are always reference frequency values, and the Y values represent the test frequency.

Mathematical treatment

Programme OSR reads the X values (independent variable) and the Y values (dependent variable).

It is written

$$Z_{ij} = X_i^j \quad \text{where } i = 1, \ldots n \text{ (number of values)}$$

$$j = 1 \ldots k \text{ (polynomial degree)}$$

Product sums are calculated after the mean values have been subtracted from Z_{ij} and Y_i

$$W = \sum_{k=1}^{n} (Z_{ki} - \bar{Z}_i)(Z_{kj} - \bar{Z}_j)$$

$$t = \sum_{k=1}^{n} (Z_{ki} - \bar{Z}_i)(Y_k - \bar{Y})$$

$$S = \sum_{k=1}^{n} (Y_k - \bar{Y})$$

Regression coefficients are obtained by transposing the matrix W and multiplying it with t.

Value F shows how well the polynomial can be calculated from the material given. The table yields.

$F(1\ 60) = 7.08$ ($P = 0.01$) which means that the material is statistically reliable.

RESULTS

A General aspects

The test subjects carried out the equal loudness comparison at 20 40 60 and 80 dB sensation levels Ten subjects took part in comparison at the maximum level The sensation levels are approximative considering the described rounding off of the threshold level to the nearest 5 dB

The method of adjustment with the self recording audiometer used to carry out the comparison requires greater concentration by the test subject than the constant stimulus method or the method of limits common in the earlier studies. Some test subjects could not manage to carry out the comparison within one minute their Békésy excursions showing a continuous, either rising or falling trend One test subject had to be excluded because he on re-testing repeatedly chose a loudness level differing by up to 15—20 dB from his earlier result

Probably most of the above exclusions must be attributed to fatigue for the studies had to be carried out in the evening after the day s work Normally however the test subject on re-testing even after an interval of several days again chose the earlier balancing level with an accuracy of ±5 dB Having achieved a balance most test subjects maintained it with an accuracy of 0—5 dB

B Threshold measurements

Threshold measurements usually took c 45—60 minutes including the initial familiarisation with the test and the 10-minute interval after testing the first ear A mean value curve was calculated for the material from these measurements based on the arithmetic means (Table 2) The two ears displayed an equal hearing ability at low frequencies up to 1000 Hz but at high frequencies the left ear was slightly better (Fig 3) The difference was over 3 dB at its maximum at 3000 Hz, but t test showed that it was not significant When the standard deviation of the threshold values was calculated the much better than average values of the youngest test subject (14 yrs) attracted attention When he was excluded the standard deviations were clearly reduced This subject is, however included in the study and its statistical treatment since despite his young age he made the comparisons without the slightest difficulty

Table 2. *Mean values of thresholds relative to 0 0002 dyn/cm*

Frequency	Right ear		Left ear	
	mean	SD	mean	SD
125	47 6	9 9	49 4	11 1
250	26 9	8 7	25 9	10 5

6000	14 4	7.5	17.3	8.5
8000	13.2	9 6	13 2	8 8

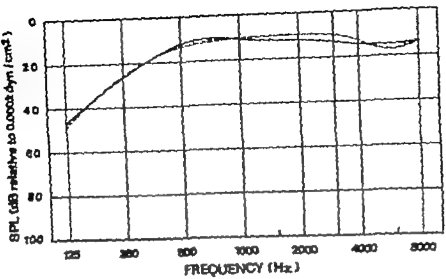

Fig 3. The continuous line is the threshold curve of the right ear and the broken line that of the left ear

C Amplitudes of balancing excursions

1 *Threshold level.* In threshold determinations the amplitudes of Békésy excursions ranged from 5 to 19 dB and in the balancing periods from 3 to 23 dB.

Table 3 shows that the excursions were slightly greater at low frequencies, but no significant differences appeared. Neither were significant differences noted between the left and right ears.

2. *Suprathreshold level.* The amplitudes of balancing excursions (all averaged) tended to diminish at high comparison levels (Table 4). The difference was significant in the monaural study between levels 20 and 60, 20 and 80 and 20 and the maximal sensation level. In the binaural study the difference was significant between sensation levels 20 and 60, and 20 and 80 dB. At the maximal level the amplitude of the excursions again tended to increase. Between the mon- and binaural study no significant differences were noted in the excursion amplitudes at any level ($p \leq 0.05$)

Table 3. *Average amplitudes of threshold excursions (dB)*

Frequency	Right ear		Left ear	
	mean	SD	mean	SD

RESULTS

A General aspects

The test subjects carried out the equal loudness comparison at 20 40 60 and 80 dB sensation levels Ten subjects took part in comparison at the maximum level The sensation levels are approximative considering the described round ing off of the threshold level to the nearest 5 dB

The method of adjustment with the self *recording audiometer* used to *carry out* the comparison requires greater concentration by the test subject than the constant stimulus method or the method of limits common in the earlier studies Some test subjects could not manage to carry out the comparison within one minute their Békésy excursions showing a continuous, either rising or falling trend One test subject had to be excluded because he on re testing repeatedly chose a loudness level differing by up to 15—20 dB from his earlier result

Probably most of the above exclusions must be attributed to fatigue for the studies had to be carried out in the evening after the day s work Normally however the test subject on re-testing even after an interval of several days again chose the earlier balancing level with an accuracy of ±5 dB Having achieved a balance most test subjects maintained it with an accuracy of 0—5 dB

B Threshold measurements

Threshold measurements usually took c. 45—60 minutes Including the initial familiarisation with the test and the 10-minute interval after testing the first ear A mean value curve was calculated for the material from these measurements based on the arithmetic means (Table 2) The two ears displayed an equal hearing ability at low frequencies up to 1000 Hz but at high frequencies the left ear was slightly better (Fig 3) The difference was over 3 dB at its maximum at 3000 Hz, but t test showed that it was not significant When the standard deviation of the threshold values was calculated the much better than average values of the youngest test subject (14 yrs) attracted attention When he was excluded the standard deviations were clearly reduced This subject is however included in the study and its statistical treatment since despite his young age he made the comparisons *without the slightest difficulty*

C Amplitudes of balancing excursions

1 *Threshold level.* In threshold determinations the amplitudes of Békésy excursions ranged from 5 to 19 dB and in the balancing periods from 3 to 23 dB

Table 3 shows that the excursions were slightly greater at low frequencies, but no significant differences appeared. Neither were significant differences noted between the left and right ears.

2. *Suprathreshold level.* The amplitudes o balancing excursions (all averaged) tended t diminish at high comparison levels (Table 4) The difference was significant in the monaura study between levels 20 and 60 20 and 80 an 20 and the maximal sensation level. In th binaural study the difference was significan between sensation levels 20 and 60 and 20 an 80 dB At the maximal level, the amplitude c the excursions again tended to increase. Betwee the mon and binaural study no significar differences were noted in the excursion ampl tudes at any level ($p \leq 0.05$)

D Matching functions between pure tones

When matching functions between pure tones were drawn from the values calculated by computer the initial point (threshold values) of the functions was taken as the arithmetic mean threshold value defined above This was necessary because in this way the first curve of the equal loudness-level contours drawn with the aid of matching functions became indentical with the threshold curves. The computer calculated the mean values of both frequencies for the system of coordinates with the least squares method in both directions from the centre of the curve. For this reason the points at both ends of the function are partially determined also by the location of the points along the curve. When the computer-calculated threshold values were compared with the arithmetic threshold values, the difference was found to be at the most 2—3 dB and in many cases the values were the same.

The figures 4—7 show the graphs of the matching functions between pure tones.

As was stated (p. 11) the sensation levels are approximative. For this reason the standard deviation values were not calculated separately for each sensation level of the matching functions, but the computer programme was so selected that standard deviation values were obtained directly for the whole curve (Table 7) The SD values at low frequencies are distinctly higher when they serve as the reference tone

E. Equal-loudness level contours

1 Phon contours

The loudness level of a given tone in terms of phons is equal to the sound pressure level (re 0.0002 dyn/cm²) of a 1000 Hz tone that to subjects with normal hearing sounds equally loud as the tone concerned. Phon contours were drawn with the aid of frequency pairs in which 1000 Hz was the reference tone The threshold contour is at the same time the 0 phon contour A comparison of the mon- and binaural phon contours reveals that the former needed slightly less intensity for equal loudness than the binaural test at both low and high frequencies (Fig 8)

2. Other equal-loudness-level contours

Equal-loudness-level contours were drawn with the aid of the frequency pairs in which the reference tone was not 1000 Hz (Figs. 9—11) A comparison of the phon contours and other equal-loudness contours reveals that the contours have a similar slope as long as the reference tone has a frequency of 500 Hz or more On the other hand the equal-loudness contours drawn with 125 and 250 Hz as reference tones have a straighter course than the phon contours. Furthermore all the equal-loudness level curves show the same phenomenon as the phon curves, viz. that the monaural matching curve runs above the corresponding binaural curve

3 *Amplitude comparison between neighbouring and widely separated frequencies* Table 5 shows the average amplitudes of the two groups of frequencies. Frequency pairs 125—250 250—500 1000—2000 1000—500 2000—3000 on the one hand and 1000—8000 2000—8000 500—4000 250—4000 125—2000 on the other were selected for the mean value comparison of the excursions. Although all test subjects found it easier to compare neighbouring frequencies than those further apart no statistically demonstrable differences in the amplitude of excursions existed between the groups compared

4 *Amplitude comparison between low or high frequencies* Statistically using the arithmetic mean no significant differences were noted in the amplitude of balancing excursions of the high frequency pairs on the one hand and the low ones on the other (Table 6) Frequency pairs 4000—8000 4000—6000 3000—8000 3000—6000 3000—4000 were selected for the former and 250—500 125—2000 125—1000 125—500 125—250 for the latter group Comparison was carried out at all sensation levels.

Table 6 reveals clearly the same trend as Table 4 viz. that the amplitude of the excursions diminishes at the higher levels of comparison

Table 5 *Average amplitudes of balancing excursions (dB) with neighbouring and widely separated frequencies*

D Matching functions between pure tones

When matching functions between pure tones were drawn from the values calculated by computer the initial point (threshold values) of the functions was taken as the arithmetic mean threshold value defined above. This was necessary because in this way the first curve of the equal-loudness-level contours drawn with the aid of matching functions became indentical with the threshold curves. The computer calculated the mean values of both frequencies for the system of coordinates with the least squares method in both directions from the centre of the curve. For this reason the points at both ends of the function are partially determined also by the location of the points along the curve. When the computer-calculated threshold values were compared with the arithmetic threshold values, the difference was found to be at the most 2—3 dB and in many cases the values were the same.

The figures 4—7 show the graphs of the matching functions between pure tones.

As was stated (p. 11) the sensation levels are approximative. For this reason the standard deviation values were not calculated separately for each sensation level of the matching functions but the computer programme was so selected that standard deviation values were obtained directly for the whole curve (Table 7). The SD values at low frequencies are distinctly higher when they serve as the reference tone.

E Equal-loudness-level contours

1 Phon contours

The loudness level of a given tone in terms of phons is equal to the sound pressure level (re 0.0002 dyn/cm^2) of a *1000* Hz tone that to subjects with normal hearing sounds equally loud as the tone concerned. Phon contours were drawn with the aid of frequency pairs in which 1000 Hz was the reference tone. The threshold contour is at the same time the 0 phon contour. A comparison of the mon. and binaural phon contours reveals that the former needed slightly less intensity for equal loudness than the binaural test at both low and high frequencies (Fig. 8).

2. Other equal-loudness-level contours

Equal-loudness-level contours were drawn with the aid of the frequency pairs in which the reference tone was not 1000 Hz (Figs. 9—11). A comparison of the phon contours and other equal-loudness contours reveals that the contours have a similar slope as long as the reference tone has a frequency of 500 Hz or more. On the other hand, the equal-loudness contours drawn with 125 and 250 Hz as reference tones have a straighter course than the phon contours. Furthermore, all the equal-loudness level curves show the same phenomenon as the phon curves, viz. that the monaural matching curve runs above the corresponding binaural curve.

F Scale graph

The illustrations are in principle composed in the same way as Fowler's scale graph (Figs 12—15) The graphs are so drawn that the threshold values of the two frequencies compared are given as zero after which mutually corresponding values at 10 dB intervals have been chosen from the matching function In the columnar diagram the first frequency is the reference tone. Not all columns reach the 100 dB sensation level mainly because of the high threshold value of low frequencies and partly because of the inadequate power of the equipment. Comparison of the monaural and binaural ladder grams again shows that the monaural test tone levels are higher than the corresponding binaural but the trend is similar in both comparisons

DISCUSSION

A Thresholds

The frequencies compared had the stimulus duration of 400 msec with a pause of the same length There is a complete agreement (Munson 1947 Garner 1947 Wittich 1966) that these tones are sufficiently long to reach their full loudness value The rise-decay time of the stimulus was 30 msec, a time sufficient to elimi nate "switching transients . The stimuli thus were adequate for loudness level comparisons

The threshold determinations were carried out with continuous tones because of a background noise produced by the interrupter This was not considered to affect the test results as it has been shown that threshold values on normal subjects using continuous or pulsated tone are overlapping (Palva 1956 1957 Corso & Wilson 1957 Jokinen 1969) In the present series no adaptation was noted in the slope of the threshold recordings traced at a fixed frequency Abnormal adaptation to a continuous tone is so uncommon in normal subjects that it need not be expected to occur although the phenomenon must be kept in mind (Palva & Palva 1963)

The originally planned comparison levels did not hold good in detail because the measured thresholds were rounded to the nearest 5 dB This however does not affect the course of the matching function between the various pure tones. Threshold values have their individual readings for different persons and the sensation levels based on them therefore would in no case be on the same SPL readings. Ward (1966) points out that neither SL nor SPL is usually related to loudness in exactly the same way for the two ears at the same frequency or for two frequencies on the same ear

The present threshold SPL values are throughout slightly higher than the values reported from earlier equal loudness level studies An exception is made by the frequencies above 1000 Hz, on which Ross (1967) had the highest thresholds of all These differences have some bearing upon the method used for threshold testing and upon the point designated as the threshold in self recording audiometry Other differences are due to the methods of using either minimum audible field or minimum audible pressure values. This amounts to about 6 dB (British Standard 2497 1954) which is practically constant throughout the frequency range This is also in agreement with the data by Sivian & White (1933)

The mean amplitudes of the self recording automatic threshold excursions obtained at threshold vary within the range of 7 9 and 10 7 A similar result was arrived at by Palva (1957) who found that normal subjects occasionally showed amplitudes below 5 dB and the 20 dB limit was seldom exceeded In the present study the values ranged from 5 to 19 dB Jokinen (1969) also reported similar results The size of the excursions at suprathreshold comparison levels was significantly smaller at some of the levels but no frequency dependence was observed

B Matching functions between pure tones

Ross (1967) reconstructed the matching functions from the previous studies corresponding to a medium frequency (e.g. 1000 Hz) and one or two low frequencies. He stated that the matching functions from the three earlier studies showed a double inflection, and the data from Zwicker & Feldtkeller (1955) showed a slight double inflection. In the present study a third-power curve was chosen to illustrate the matching functions since it seemed to suit the practical purposes best. Trial runs of the results were carried out with higher equations, but the curves seemed to become too curly and they apparently did not reflect the true form.

A comparison showed that the differences between mon- and binaural curves (Figs. 4—7) were small. The most noticeable difference was in the pair 4000—8000 Hz in which the matching function in the monaural test lays below the basic line. The double inflection of the curves was most distinct in the monaural test, and especially at the low frequencies, below 1000 Hz. At these frequencies the asymptotic approach of the function to the 45-degree line serving as the basic line was clear. This phenomenon in normal ears is similar to Fowler's graph of the recruitment in hearing impairment and is a constant finding in all studies with loudness contour matches.

C Phon contours

Fletcher & Munson (1933) chose the threshold values so that the 0 phon contour at 1000 Hz passed through 10- W/cm² or approximately the 0.0002 dyn/cm value. The curve so obtained was 3—4 dB below the average values measured in their series. Furthermore it was seen that the contour was not uniformly below the experimental alues but approached the experimental threshold contour at the low frequencies. Nor did Churcher & King (1937) draw their 0 phon contour through the values obtained at threshold determinations (Robinson & Dadson 1956)

The threshold values or 0 phon contour obtained in the present study are closest to those obtained by Zwicker & Feldtkeller (1955) At low frequencies the correlation is good, but at high frequencies the present values are c. 5 dB below those quoted in their paper although they are smaller than the values obtained by Ross (1967)

The present phon contours at low frequencies and low sound-pressure levels distinctly approached each other A phenomenon resembling recruitment emerged most clearly at 125 Hz, between 60—80 dB. A similar loudness recruitment has also been reported from earlier equal loudness determinations. With values exceeding 80 dB the phon contours were evenly spaced at 10 dB from one another

When the phon contours of the present study were compared with those of Fletcher & Munson (1933) a dissimilar course was seen at high frequencies (Fig. 16) It must be taken into account that at the high frequencies, 600—8000 Hz, sound reproduction by the receivers, however was not ideal (Fig 2) The contours obtained by latter authors had the shape of a gently curved letter U in the ascending decibel grading and those by Zwicker & Feldtkeller (1955) were similar The most remarkable difference from their curves was that the present contours turned downward at 6000 Hz. A similar result was reported by Ross (1967) At the low frequencies, the curves obtained in the present study approach each other more steeply than those reported from other studies. At high sound pressure levels the differences diminished, and the 80 phon curves were already almost parallel.

DISCUSSION

A Thresholds

The frequencies compared had the stimulus duration of 400 msec with a pause of the same length There is a complete agreement (Munson 1947 Garner 1947 Wittich 1966) that these tones are sufficiently long to reach their full loudness value The rise-decay time of the stimulus was 30 msec a time sufficient to elimi nate switching transients" The stimuli thus were adequate for loudness level comparisons

The threshold determinations were carried out with continuous tones because of a background noise produced by the interrupter This was not considered to affect the test results as it has been shown that threshold values on normal subjects, using continuous or pulsated tone are overlapping (Palva 1956 1957 Corso & Wilson 1957 Jokinen 1969) In the present series no adaptation was noted in the slope of the threshold recordings traced at a fixed frequency Abnormal adaptation to a continuous tone is so uncommon in normal subjects that it need not be expected to occur although the phenomenon must be kept in mind (Palva & Palva 1963)

The originally planned comparison levels did not hold good in detail because the measured thresholds were rounded to the nearest 5 dB This however does not affect the course of the matching function between the various pure tones. Threshold values have their individual readings for different persons, and the sensation levels based on them therefore would in no case be on the same SPL readings. Ward (1966) points out that neither SL nor SPL is usually related to loudness in exactly the same way for the two ears at the same frequency or for two frequencies on the same ear

The present threshold SPL values are throughout slightly higher than the values reported from earlier equal loudness level studies An exception is made by the frequencies above 1000 Hz, on which Ross (1967) had the highest thresholds of all These differences have some bearing upon the method used for threshold testing and upon the point designated as the threshold in self recording audiometry Other differences are due to the methods of using either minimum audible field or minimum audible pressure values. This amounts to about 6 dB (British Standard 2497 1954) which is practically constant throughout the frequency range This is also in agreement with the data by Sivian & White (1933)

The mean amplitudes of the self recording automatic threshold excursions obtained at threshold vary within the range of 7 9 and 10 7 A similar result was arrived at by Palva (1957) who found that normal subjects occasionally showed amplitudes below 5 dB and the 20 dB limit was seldom exceeded In the present study the values ranged from 5 to 19 dB Jokinen (1969) also reported similar results The size of the excursions at suprathreshold comparison levels was significantly smaller at some of the levels but no frequency dependence was ob served

contours revealed that they followed very similar slopes, although they were drawn for different reference tones. An exception was made by 125 Hz contours where this similarity was lacking. By and large the similarity of the contours for different reference tones is evidence of the precision and validity of the comparisons made.

The phon contours and other loudness level contours were also mutually compared, and the latter were found to have a considerably straighter course. The phenomenon reminiscent of loudness recruitment at the low end of the phon contours was clearly visible only in the contours drawn with 125 Hz as the reference tone. This straightening of the curves when low frequency was taken as the reference tone may partly be due to the greater difference limen at low frequencies, described by Riesz (1928). One indication of the somewhat less accurate loudness comparison at low frequencies was the larger standard deviation (Table 7). This is especially evident in the binaural comparison. It might then be expected that, as an indication of a less accurate comparison at low frequencies than at high, the Békésy excursions would be larger at the low frequencies. However this was not the case (Table 6).

When one looks for the causes of the differences between the phon contours and equal loudness-level contours at low frequencies, the most obvious seems to be the greater difference limen at the low frequencies, which was mentioned above. As a result, in a loudness comparison with a low frequency as the reference tone, the variation possibilities of the test tone being judged equally loud (by the adjustment method) are greater than in the opposite case when the higher frequency is used as reference tone.

No suitable statistical means of measuring the significance of differences was found for the mutual comparison of the monaural and binaural loudness matching. Usually the monaural test needed smaller sound pressures for equal loudness with 1000 Hz tone than the corresponding binaural test. A factor possibly entering into the question might be the central components associated with the physiology of hearing. This is doubtful however since even the binaural test involves, in principle monaural hearing for the tones were given alternately and not simultaneously to both ears. Furthermore no absolute regularity was observable in the differences between the contours.

Many authors have emphasized that the comparison in Reger's test should not be carried out with frequencies more than two octaves apart (Lidén 1962). Table 5 shows, however that there were no statistically significant differences in the amplitudes of balancing excursions between pure tones close to each other and those more than two octaves apart. This can be taken as evidence that the test subjects showed no uncertainty in their selection of the equal-loudness-level although they found the comparison of closely spaced frequencies easier.

E Scale graph

As already mentioned the results obtained from monaural loudness level comparison studies for demonstration of a recruitment phenomenon had to be taken from the equal-loudness level contours. Comparing is slow but the task can be facilitated with the aid of the scale graph method developed by Fowler (1936). The equal-loudness level curves measured on normal subjects can be converted into a laddergram similar to that used for the loudness level comparisons with one frequency. This time the comparison involves two different frequencies, with the reference tone on the left vertical axis and the test tone on the right.

The illustrations on pages 32—36 have been redrawn by placing the 0 dB sensation level at the top of the scale. This presentation is used if the scale graph is drawn on ordinary audiogram paper superimposed on the audiogram. Most often however in ordinary clinical work the scale graph is presented with the sensation level of 0 dB at the bottom. The first connecting line between the vertical axes is obtained by connecting the threshold values together. The next lines in the laddergram are obtained in the same way as was described in the chapter

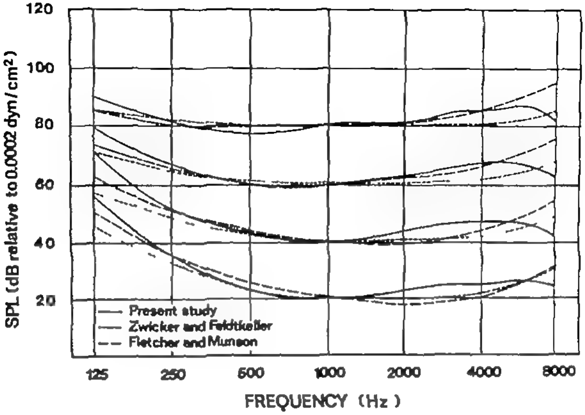

Fig 16. Comparison of three phon cotour studies

D Equal loudness level contours

The original study plan omitted 1000 Hz as a test tone when the matched pairs of pure tones were selected since the inclusion of 1000 Hz as a reference tone in the comparison was considered sufficient An analysis of the results revealed that the course of equal loudness level contours was similar to that of the binaural phon contours whereas discrepancies were noted in the monaural phon contours and other monaural equal loudness level contours. For this reason 125 250 and 500 Hz were once again compared with 1000 Hz in ten test subjects. It was found that the values obtained closely followed the previously drawn equal loudness level contours This procedure at the same time, provided conclusive evidence of the reliability of the loudness comparison test in repetitions

The monaural phon contours and other monaural equal loudness level contours showed throughout lower loudness levels than the binaural At the low end the monaural phon contours ran slightly closer to each other than the binaural These discrepancies were at first suspected to be due to a calibration error but determinations after physical checks gave values identical with those obtained in the original measurement In addition the discrepancies emerged most clearly only after 50 phons i e on the higher sound pressure levels. Also with 250 and 500 Hz as reference tone, the mon and binaural equal loudness level contours were similar

Comparison of the equal loudness level

contours revealed that they followed very similar slopes, although they were drawn for different reference tones. An exception was made by 125 Hz contours where this similarity was lacking. By and large the similarity of the contours for different reference tones is evidence of the precision and validity of the comparisons made.

The phon contours and other loudness level contours were also mutually compared, and the latter were found to have a considerably straighter course. The phenomenon reminiscent of loudness recruitment at the low end of the phon contours was clearly visible only in the contours drawn with 125 Hz as the reference tone. This straightening of the curves when low frequency was taken as the reference tone may partly be due to the greater difference limen at low frequencies, described by Riesz (1928). One indication of the somewhat less accurate loudness comparison at low frequencies was the larger standard deviation (Table 7). This is especially evident in the binaural comparison. It might then be expected that, as an indication of a less accurate comparison at low frequencies than at high, the Békésy excursions would be larger at the low frequencies. However, this was not the case (Table 6).

When one looks for the causes of the differences between the phon contours and equal loudness-level contours at low frequencies, the most obvious seems to be the greater difference limen at the low frequencies, which was mentioned above. As a result, in a loudness comparison with a low frequency as the reference tone, the variation possibilities of the test tone being judged equally loud (by the adjustment method) are greater than in the opposite case when the higher frequency is used as reference tone.

No suitable statistical means of measuring the significance of differences was found for the mutual comparison of the monaural and binaural loudness matching. Usually the monaural test needed smaller sound pressures for equal loudness with 1000 Hz tone than the corresponding binaural test. A factor possibly entering into the question might be the central components associated with the physiology of hearing. This is doubtful, however, since even the binaural test involves, in principle, monaural hearing for the tones were given alternately and not simultaneously to both ears. Furthermore no absolute regularity was observable in the differences between the contours.

Many authors have emphasized that the comparison in Reger's test should not be carried out with frequencies more than two octaves apart (Lidén 1962). Table 5 shows, however, that there were no statistically significant differences in the amplitudes of balancing excursions between pure tones close to each other and those more than two octaves apart. This can be taken as evidence that the test subjects showed no uncertainty in their selection of the equal loudness-level, although they found the comparison of closely spaced frequencies easier.

E Scale graph

As already mentioned, the results obtained from monaural loudness level comparison studies for demonstration of a recruitment phenomenon had to be taken from the equal-loudness-level contours. Comparing is slow, but the task can be facilitated with the aid of the scale graph method developed by Fowler (1936). The equal-loudness level curves measured on normal subjects can be converted into a laddergram similar to that used for the loudness level comparisons with *one* frequency. This time the comparison involves two *different frequencies*, with the reference tone on the left vertical axis and the test tone on the right.

The illustrations on pages 32—36 have been redrawn by placing the 0 dB sensation level at the top of the scale. This presentation is used if the scale graph is drawn on ordinary audiogram paper superimposed on the audiogram. Most often, however, in ordinary clinical work the scale graph is presented with the sensation level of 0 dB at the bottom. The first connecting line between the vertical axes is obtained by connecting the threshold values together. The next lines in the laddergram are obtained in the same way as was described in the chapter

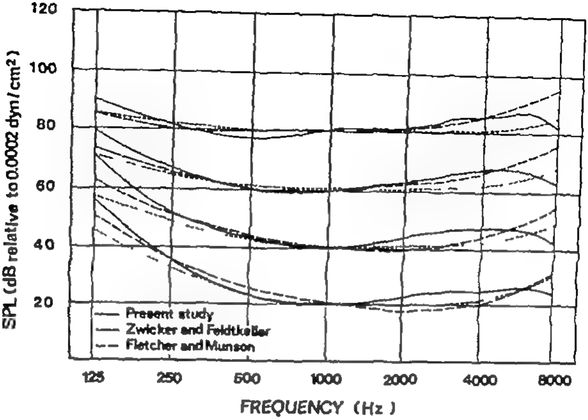

Fig 16 Comparison of three phon cotour studies

D Equal loudness level contours

The original study plan omitted 1000 Hz as a test tone when the matched pairs of pure tones were selected since the inclusion of 1000 Hz as a reference tone in the comparison was considered sufficient An analysis of the results revealed that the course of *equal loudness level contours* was similar to that of the binaural phon contours whereas discrepancies were noted in the monaural phon contours and other monaural equal loudness level contours. For this reason 125 250 and 500 Hz were once again compared with 1000 Hz in ten test subjects. It was found that the values obtained closely followed the previously drawn equal loudness level contours This procedure at the same time provided conclusive evidence of the reliability of the loudness comparison test in repetitions

The monaural phon contours and other monaural equal loudness level contours showed throughout lower loudness levels than the binaural At the low end, the monaural phon contours ran slightly closer to each other than the binaural These discrepancies were at first *suspected to be due to a calibration error* but determinations after physical checks gave values identical with those obtained in the original measurement In addition the discrepancies emerged most clearly only after 50 phons i e on *the higher sound pressure levels Also with 250* and 500 Hz as reference tone the mon and binaural equal loudness level contours were similar

Comparison of the equal-loudness level

contours revealed that they followed very similar slopes, although they were drawn for different reference tones. An exception was made by 125 Hz contours where this similarity was lacking. By and large the similarity of the contours for different reference tones is evidence of the precision and validity of the comparisons made.

The phon contours and other loudness level contours were also mutually compared and the latter were found to have a considerably straighter course. The phenomenon reminiscent of loudness recruitment at the low end of the phon contours was clearly visible only in the contours drawn with 125 Hz as the reference tone. This straightening of the curves when low frequency was taken as the reference tone may partly be due to the greater difference limen at low frequencies, described by Riesz (1928). One indication of the somewhat less accurate loudness comparison at low frequencies was the larger standard deviation (Table 7). This is especially evident in the binaural comparison. It might then be expected that, as an indication of a less accurate comparison at low frequencies than at high, the Békésy excursions would be larger at the low frequencies. However, this was not the case (Table 6).

When one looks for the causes of the differences between the phon contours and equal loudness-level contours at low frequencies, the most obvious seems to be the greater difference limen at the low frequencies which was mentioned above. As a result, in a loudness comparison with a low frequency as the reference tone, the variation possibilities of the test tone being judged equally loud (by the adjustment method) are greater than in the opposite case when the higher frequency is used as reference tone.

No suitable statistical means of measuring the significance of differences was found for the mutual comparison of the monaural and binaural loudness matching. Usually the monaural test needed smaller sound pressures for equal loudness with 1000 Hz tone than the corresponding binaural test. A factor possibly entering into the question might be the central components associated with the physiology of hearing. This is doubtful, however, since even the binaural test involves, in principle, monaural hearing, for the tones were given alternately and not simultaneously to both ears. Furthermore, no absolute regularity was observable in the differences between the contours.

Many authors have emphasized that the comparison in Reger's test should not be carried out with frequencies more than two octaves apart (Lidén 1962). Table 5 shows, however, that there were no statistically significant differences in the amplitudes of balancing excursions between pure tones close to each other and those more than two octaves apart. This can be taken as evidence that the test subjects showed no uncertainty in their selection of the equal loudness-level, although they found the comparison of closely spaced frequencies easier.

E. *Scale graph*

As already mentioned, the results obtained from monaural loudness level comparison studies for demonstration of a recruitment phenomenon had to be taken from the equal-loudness-level contours. Comparing is slow, but the task can be facilitated with the aid of the scale graph method developed by Fowler (1936). The equal-loudness level curves measured on normal subjects can be converted into a laddergram similar to that used for the loudness level comparisons with one frequency. This time the comparison involves two different frequencies, with the reference tone on the left vertical axis and the test tone on the right.

The illustrations on pages 32—36 have been redrawn by placing the 0 dB sensation level at the top of the scale. This presentation is used if the scale graph is drawn on ordinary audiogram paper superimposed on the audiogram. Most often, however, in ordinary clinical work the scale graph is presented with the sensation level of 0 dB at the bottom. The first connecting line between the vertical axes is obtained by connecting the threshold values together. The next lines in the laddergram are obtained in the same way as was described in the chapter

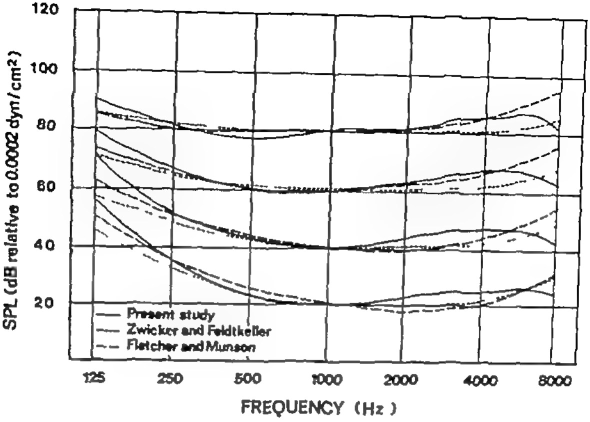

Fig 16 Comparison of three phon cotour studies

D Equal loudness level contours

The original study plan omitted 1000 Hz as a test tone when the matched pairs of pure tones were selected since the inclusion of 1000 Hz as a reference tone in the comparison was considered sufficient An analysis of the results revealed that the course of equal loudness level contours was similar to that of the binaural phon contours whereas discrepancies were noted in the monaural phon contours and other monaural equal loudness level contours. For this reason 125 250 and 500 Hz were once again compared with 1000 Hz in ten test subjects It was found that the values obtained closely followed the previously drawn equal loudness level contours This procedure at the same time provided conclusive evidence of the reliability of the loudness comparison test in repetitions.

The monaural phon contours and other monaural equal loudness level contours showed throughout lower loudness levels than the binaural At the low end, the monaural phon contours ran slightly closer to each other than the binaural These discrepancies were at first suspected to be due to a calibration error but determinations after physical checks gave values identical with those obtained in the original measurement In addition the discrepancies emerged most clearly only after 50 phons i e on the higher sound pressure levels. Also with 250 and 500 Hz as reference tone the mon and binaural equal loudness level contours were similar

dealing with Fowler s test techniques (p 5) These normal loudness level comparisons are given below to facilitate the clinical evaluation of Reger s test made of the same frequency pairs

1 125 Hz as reference tone (125—250 125—500 125—1000 and 125—2000 H)

It is seen from Fig 17 drawn with 125 Hz as the reference tone that a considerably higher sensation level is required of the test tone to attain the same loudness as the refernce tone The higher the sensation level at which the comparison is made the greater is the difference Due to the high threshold value of 125 Hz comparison could only be made at the sensation level of 60 dB due to the maximum limits of the audiometer

In both mon and binaural testing the difference was 15 dB for the pair 125—250 Hz. With the other frequency pairs the difference in the monaural test was c 20 dB and the binaural test 25 dB

2. 250 H as reference tone (250—500, 250—1000 250—2000 and 250—4000 Hz)

Fig 18 shows that at low sound-pressure levels, the same loudness is obtained at almost identical sensation levels for various test tones, but the higher the test levels chosen the more distinct become the differences At 80 dB sensation level the test tone must have an almost 10 dB higher SL to achieve the same loudness at all compared frequencies

3 500 Hz as reference tone (500—1000 500—2000 and 500—4000 Hz)

In comparison with 500 Hz as reference tone the same loudness is obtained for the three compared frequencies at approximately the same sensation levels (Fig 19) The difference is at its maximum in a monaural comparison of 500—4000 Hz. The difference however is not significant and it does not exceed 5 dB even if the SL is 100 dB

4 1000 H. as reference tone (1000—125 1000—250 1000—500 1000—2000 1000—3000 1000—4000 1000—6000 and 1000—8000 Hz)

Scale graphs obtained for the test pairs 1000—125 and 1000—250 Hz are in principle similar to those for 125—1000 and 250—1000 Hz except that the direction of the connecting lines is reversed while the differences between sensation levels are of the same order of magnitude (Fig 20)

For the frequency pairs 1000—500 1000—2000 (Fig 20) 1000—3000 and 1000—6000 Hz (Fig 21) the same loudness is obtained at practically identical sensation levels In frequency pairs 1000—4000 and 1000—8000 Hz on the other hand the test tone has an SL more than 5 dB lower than that of the reference tone when tracing near the maximum limits of the audiometer in the monaural study (Fig 21) In the binaural test the difference is not so distinct.

5 2000 H. as reference tone (2000—3000, 2000—4000 2000—6000 and 2000—8000 H.)

No test pair of the scale graphs drawn with 2000 Hz as reference tone shows a difference exceeding 5 dB between sensation levels giving the same loudness levels (Fig 22) Thus identical sensation levels give the same loudness levels with an accuracy adequate for clinical work

6 3000 H as reference tone (3000—4000 3000—6000 and 3000—8000 H)

3000 Hz as reference tone also gives equal-loudness levels as the above test tones at approximately the same sensation levels (Fig 23)

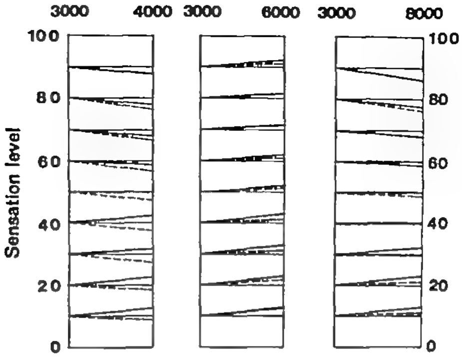
Fig 24

7. 4000 Hz as reference tone (4000—6000 and 4000—8000 Hz)

The sensation levels of the reference and test tones do not differ by more than 5 dB, and in clinical work, with a view to Reger's test, identical loudness is normally obtained at the same sensation level (Fig. 24).

As seen from the various scale graphs on normal subjects, a number of the frequencies compared gave identical loudness levels at the same sensation level. Some low frequencies however gave the same loudness level even at considerably different sensation levels and for these frequencies the clinician should compare the Reger test results with those obtained on normal subjects.



Scale graph 3000Hz as reference tone

Fig 23

Fig 24

could not be used alternatively in the loudness comparison, since the results obtained differed significantly ($p \leq 0.01$) With 1000 Hz as the reference tone there a greater difference in sound intensity before equal loudness was reached. The only exception was made by the pair 125—1000 Hz and 1000—125 Hz in the binaural comparison, no statistical differences were elicited between them ($p \leq 0.01$)

In the pair 125—250 Hz the test tone at the 60 dB sensation level, had to have a 15 dB higher sensation level for equal loudness to be achieved. In pairs 125—500 125—1000 and 125—2000 Hz the difference was 20—25 dB respectively

In pairs 250—500 250—1000 250—2000 and 250—4000 Hz at the sensation level of 80 dB the difference was almost 10 dB

Loudness comparison with binaural techniques revealed that the test tone required a higher intensity than in the monaural test to reach the same loudness. No cause to account for this phenomenon could be traced.

CONCLUSIONS

In the comparison of loudness levels at different frequencies with automatic testing the technique is somewhat more demanding than with the other comparison methods and a few subjects had real difficulties in the test However only one showed such inconsistency that he could not be used in the series In measurements carried out on the reported series of 14 test subjects the threshold excursions of the Békésy audiogram ranged from 5 to 19 dB The mean values of these excursions for different frequencies were within the range of 7 9—10 7 dB At the suprathreshold levels the excursions became significantly smaller at higher (60 and 80) SLs but were independent of the compared frequencies.

Reger s test can well be carried out using *automatic test techniques for frequencies* differing by more than two octaves. all test subjects in the series managed the comparison of all frequency pairs without much difficulty Statistically (Table 5) no significant differences could be found in the amplitudes of the balancing excursions in frequency pairs close to one another and those widely separated.

The phon contours obtained with automatic technique in the present study differed from those of Fletcher & Munson (1933) which in the ascending scale have the shape of a gently curved letter U whereas those of the present study turned downward at 6000 Hz. A similar difference was also reported by Ross (1967)

At low frequencies the present study disclosed a loudness recruitment similar to that described by Fletcher & Munson (1933) but at the high frequencies all phon contours were spaced by 1 dB from one another

The equal loudness level contours were almos identical although they were drawn for differer reference tones. Comparison showed that equal loudness level contours had a straighter cours than phon contours and the loudness rec ruitment at low frequencies did not emerge i them so clearly as in the phon curves At exception was made by the contours drawn wit 125 Hz as reference tone.

Comparison of the Reger test results with the equal loudness level contours obtained on normal subjects takes less time when the values obtained are compared with normal values drawn directly into the scale graph form

500 2000 3000 and 4000 Hz as reference tones gave practically the same loudness as their test tones used in the comparison at the same sensation levels. The same is true of frequency pairs 1000—500 1000—2000 1000—3000 and 1000—6000 Hz.

In frequency pairs 1000—4000 and 1000—8000 Hz the test tone in the monaural test had a sensation level more than 5 dB lower than the reference tone when the audiometer was employed at its maximum limits.

Comparison with frequency pairs 1000—125 and 1000—250 Hz gave in principle the same result as 125—1000 and 250—1000 Hz, the scale graph columns presenting a mirror image However the frequency pairs of 125—1000 Hz and 1000—125 Hz on the one hand and 250—1000 Hz and 1000—250 Hz on the other

ACKNOWLEDGEMENTS

I would like to extend my deepest gratitude [illegible] my teacher and former chief Professor Tauno Palva, M.D Head of the Department of Otorhinolaryngology Helsinki University While holding a chair in Oulu, he suggested the theme of this study to me and with expert paedagogical skill guided me throughout the whole of my work, from the planning of the equipment of the final polishing of the manuscript.

My dept of gratitude is great also to my present chief Associate Professor Antti Palva, M.D Acting Head of the Department of Otorhinolaryngology Oulu University He gave me valuable advice and constructive criticism in the course of my work on the manuscript.

I most cordially thank Docent Aitti Salmivalli, M D audiology specialist at Turku University who expertly guided me in my work, especially by drawing my attention to the essential points in equipment and calibration.

Timo Kosonen, M.Sc. (Eng.) constructed the interrupter for my study equipment and calibrated the equipment. I am greatly indepted to him for his valuable contribution

I also wish to thank Mr Jorma Pietilä who carried out the statistical analysis of the study results, and Mr Heikki Nieminen and Mrs Seija Nieminen who prepared the numerous pictures. My warm thanks should also go to Mrs Hilkka Kontiopää, M.A for translating the Finnish manuscript, [illegible] Mrs Barbara Rikberg for checking the English, and also to Mrs Pirkko Orell for collecting the literature

SUMMARY

The purpose of the study was to compare with the aid of automatic testing techniques the loudness levels of different frequencies of pure tones, both monaurally and binaurally The risk that the comparison made by the test subject might be affected by the researcher was thus reduced to a minimum and the phon contours obtained in this way were compared with those obtained by using manual techniques. An attempt was made to facilitate the clinician s work by converting the equal loudness level contours into scale graphs with which the Reger test results can be compared in order to establish quickly whether loudness recruitment is present

The series consisted of 14 test subjects who compared tones heard through earphones at sensation levels of 20 40 60 and 80 dB finally extending the comparison to the maxi mum limits of the Békésy audiometer Holding a push button in his hand, the test subject regulated the test tone to follow the loudness of the reference tone

The comparison covered nine frequencies from the 125—8000 Hz range and a total of 28 test pairs were matched In this way almost all frequencies served in the comparison both as reference and as test tones The duration of sound impulses was 400 msec and rise decay time was 30 msec The interval between pulses was 400 msec. The time available for balancing per test pair was 1 minute

A mean value curve was calculated from the threshold measurements The two ears displayed an equal hearing ability at low frequencies up to 1000 Hz but at high frequencies the left ear was slightly better The difference was over 3 dB at its maximum at 3000 Hz, but it was not signifi cant In threshold determinations the ampli tudes of excursions ranged from 5 to 19 dB and were slightly greater at low frequencies but no significant differences appeared

The amplitudes of balancing excursions tended to diminish at high comparison levels and the difference was significant in the monaural study between levels 20 and 60 20 and 80 dB and 20 and the maximal sensation level In the binaural study the difference was signi ficant between sensation levels 20 and 60 and 20 and 80 dB

The test subjects made the comparison accurately also at frequencies two octaves apart although it was found easier to match fre- quencies that were closer to each other In the mon and binaural method of comparison the differences between the results or testing tech niques were not significant.

The phon contours obtained were similar to those of Fletcher & Munson (1933) at low frequencies but had a different course at high frequencies The difference was greatest at 6000 Hz where the Fletcher and Munson contours of the ascending scale were U shaped The contours obtained in the present study curved downwards at 6000 Hz.

The equal loudness level contours obtained were finally presented in the form of scale graphs A reduction of the initial loudness level differences normally took place in frequency pairs in which one of the two test frequencies was 125 or 250 Hz. Of the high frequency pairs balancing occurred with a sensation level difference exceeding 5 dB only at 1000—4000 Hz and 1000—8000 Hz. By comparing the Reger test results with the presented scale graphs the possible recruitment in cases of hearing impair ment can be quickly established, and is not confused with the physiological loudness rec- ruitment between frequencies

GUINEA-PIG HAIR CELL PATHOLOGY FROM OTOTOXIC ANTIBIOTICS

J Ylikoski

The selective ototoxic effect of certain aminoglycoside antibiotics has made them a useful tool for experimental pathology studies dealing with the organ of Corti. Since the earliest reports by Hinshaw and Feldman (1945) of ototoxic effects of streptomycin on the vestibular system, abundant data have accumulated regarding the quantitative and qualitative effect of these drugs upon the inner ear Today there are generally accepted concepts about the ototoxic potency of individual antibiotics and about the general pattern of damage upon the vestibular system and the organ of Corti. There are, however some great differences within species and among individual animals in the susceptibility to ototoxic agents. This is why rather large series of animals are necessary before general conclusions can be made. The commonly used method of decalcifying, serial sectioning and graphically reconstructing the organ of Corti (Guild, 1921 Schuknecht, 1953a) lacks accuracy when compared with the surface preparation technique (Retzius, 1884 Neubert, 1950 Engström et al. 1966). There are however very few studies where the surface preparation technique was used to evaluate the damage pattern in the organ of Corti after ototoxic antibiotics in a large number of experimental animals (Kohonen, 1965 Engström et al. 1966) Even in these studies hair cells within the entire cochlea were not counted. Instead one-third of each turn was presented as representative of the whole coil, thus these studies must be regarded as being purely qualitative in nature.

The material for the present investigation has been reported in part in a study where physiological and histological impairment in the inner ear of guinea-pigs was compared before and after treatment with various ototoxic antibiotics (Ylikoski, 1974 a) A large number of experimental animals was used for that study and a systematic quantitative registration of the cellular damage of almost the entire cochlea was made. In the present work a larger material has been further analysed light and electron microscopically with the aim of presenting systematically the cochlear damage pattern after treatment with three ototoxic aminoglycoside antibiotics, gentamicin kanamycin and neomycin.

MATERIAL AND METHODS

Eighty four healthy young pigmented guinea-pigs with normal pinnareflex, each weighing between 250–450 g, were studied. The hearing of most of the animals was audiometrically measured (Anderson & Wedenberg, 1965) as part of an earlier study (Ylikoski, 1974 a) dealing with audiological and morphological changes induced by ototoxic antibiotics. The left ear was then destroyed by surgical ablation prior to treatment with antibiotics in those animals which had been submitted to audiological examination. Gentamicin, kanamycin or neomycin were administered by subcutaneous injections twice daily in varying doses and for varying durations of time. The schedule for dosages and survival times for the [illegible] animals which survived treatment is given in Table I As seen in that table the animals were allowed to survive for various lengths of time after the last injection. A large number of normal guinea-pigs studied in our laboratory served as controls. All animals were decapitated while in deep chloroform anaesthesia, the temporal bones were removed

GUINEA PIG	DRUG	DOSE/day	DURATION OF TREATMENT	SURVIVAL TIME
G2 G3	Gentamicin	50mg/kg	14 days	0 days

Table 1 *The dosage schedule and survival times of 68 guinea-pigs in which cochlear pathology was studied.*

and the cochlea was fixed in 1 % or 2 % veronal buffered osmium tetroxide and embedded in Epon Each cochlea was divided with a thin saw through the modiolar axis and each half was split with a razor blade in such a way that each block contained the intact cochlear duct of one-half coil. The specimens were thinned and mounted on a glass slide basal membrane downwards (Ernstsson 1971) Each specimen was studied through a water lens 40x with a Zeiss photomicroscope equipped with the interference contrast optical system (Nomarski 1955) Each hair cell was counted and marked in a cytocochleogram as present or missing according to Engström et al. (1964) and Engström et al. (1966) An average cochleogram was prepared in which groups of five cells in the same row were counted When three or more were missing the hair cell group was marked as missing (Ylikoski et al 1973) otherwise as present" From the cytocochleogram the percentages of missing outer hair cells (OHCs) and inner hair cells (IHCs) respectively in each millimetre along the cochlear duct were counted and marked in the chart

Selected regions were reoriented and remounted in Epon and used for 0 5–1 micron thick sections for light microscopy and for thin sections which were studied in Siemens Elmiscope I transmission electron microscope after staining with uranyl acetate and lead citrate (Karnovsky 1961 Watson 1958)

A few of the cochleas were opened widely after fixation rinsed in Ringer s solution frozen in liquid propane at – 192 C and freeze-dried in vacuo The specimens were plated with gold by vac-

uum evaporation and investigated with a Cambridge Stereoscan scanning electron microscope.

RESULTS

Light microscopy

Generally each of these three antibiotics produced a similar pattern of degeneration. This always initiated as a swelling and deformation of the cell bodies and the nuclei in the first row of OHCs. When degeneration progressed the cells of this row disappeared in the basal coil and the damage spread radially to other OHC rows and spirally towards the apex.

In order to present the results of the cytoarchitectural study of the cellular destruction of the organ of Corti, the animals are grouped according to the doses of *antibiotics administered and to the extent of damage produced.*

Gentamicin

A) Gentamicin given 50 mg/kg for from 14 to 29 days or 150 mg/kg for 6 or 7 days. *This group of 19* animals was further subdivided into the following subgroups.
   1) No significant damage in the cytocochleogram (less than 1 % degenerated cells in each millimetre of the cochlea). This group consisted of five animals G 2, G 3 G 6 G 11 and G 13 (Fig. 1)

Fotnote All the dosages and total doses are given in amounts related to antibiotic base.

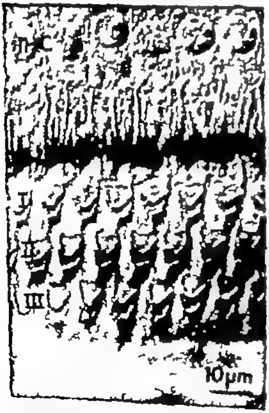

Fig. 1 Interference-contrast micrograph of the lower part of the basal coil of guinea-pig NA 2, given neomycin 250 mg/kg for 7 days and decapitated on the 7th day. The hair cell population in this cochlea was normal.

Fig. 2. Interference-contrast micrograph of a portion of the basal coil of G 12, given gentamicin 150 mg/kg for 7 days. Some cells in the first row of OHCs have collapsed.

2) Spotty degeneration distributed over the whole cochlea (*less than* 10 % missing sensory cells in each millimetre) Five animals G 10 G 12, G 14 G 15 and G 16 (Fig 2)
3) *Moderate* degeneration of the OHCs. Nine animals belonged to this group G 1 G 4 G 5 G 7 G 8 G 9 G 17 G 18 and G 19 The most severe changes were usually seen in two areas in the hook region (round window area) and in the upper basal coil. The extent of injury varied in this group from about 50 % loss of the first row of the OHCs to an almost total loss of the OHCs in the regions named. The average loss of the OHCs of *this group is seen in Fig. 3*

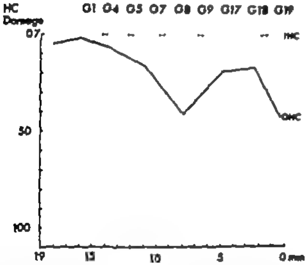

Fig. 3 Extent of mean OHC damage in 9 guinea-pigs treated with gentamicin 50 mg/kg for from 14 to 29 days as determined from the average percentage per millimetre of degenerated OHCs in each examined segment along the organ of Corti. The areas most vulnerable to degeneration are the hook region and the upper part of the basal coil. The IHCs were intact.

B) Gentamicin given 100 mg/kg for from 9 to 21 days, 18 animals.
Characteristic of this group was a great difference in damage between the three subgroups of animals.
1) Slight or no damage six animals G 22 GA 2 GA 3 GA 4 GA 12 and GA 13 One animal G 22 (Fig. 4) although given this dose for 21 days showed changes similar to those often observed in the form group treated with *50 mg/kg for* shorter period of time. The rest c this group were treated for 9 c 10 days and decapitated on th *day of the last injection.* The displayed only a subtle loss of th OHCs distributed over the entir cochlea.
2) Moderately severe degeneratio with complete loss of the OHCs i the basal half of the cochlea an varying damage to the IHCs. Thi group included 10 animals G 21 G 24 G 26, G 28 G 33 G 35 GA 6 GA 8 GA 14 and GA 16 Th damage pattern of the OHCs (Fig 5) was rather uniform starting ba *sally as a complete loss of the cell*

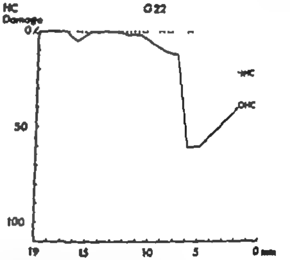

Fig. 4 Extent of hair cell damage in guinea-pig, G 22, given gentamicin 100 mg/kg for 21 days. Despite the large dosage damage was moderate.

in all three outer rows. Collapsed hair cells were replaced by the phalangeal processes of the support ing cells thus the reticular membrane was still intact. The first hair cells to appear along the basilar membrane were always in the third row these being the most resistant to ototoxic damage They appeared on the average at the 10 mm level. The second row appeared generally 1 mm higher and finally the cells of the first row commonly remained

Fig. 5

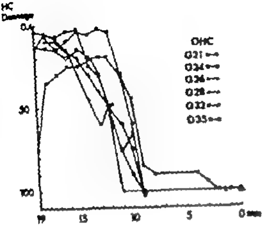

Fig. 6

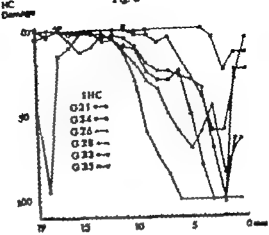

Fig. 7

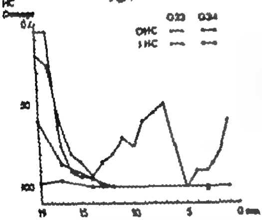

Fig. 5. The extent of OHC damage in 6 guinea-pigs given gentamicin 100 mg/kg for from 10 to 21 days was fairly uniform. All the animals suffered complete loss of OHCs in the basal cochlea. The transition from total degeneration to nearly normal configuration of OHCs occurred an average of 10 to 13 mm from the round window

Fig. 6. Extent of IHC damage in the same animals as in Fig. 5. Large variations are apparent. Early signs of damage to IHCs at the apex were noted in only one guinea-pig treated with gentamicin.

Fig. 7. Extent of OHC and IHC damage in 2 animals given gentamicin 100 mg/kg for 16 (G 23) and 14 days (G 34). Sensory cells were severely damaged in both cochleas.

from the 13 mm position upwards. The extent of damage to the IHCs varied from an intact pattern to total loss within several millimetres (Fig. 6). When all IHCs had disappeared the nerve density in the spiral osseous lamina was clearly reduced but appeared normal if the IHCs were present. In cases of advanced IHC damage the distance between the appearance of normal IHCs and the presence of near normal numbers of OHCs averaged 8 mm. In this material there was only one animal given gentamicin which displayed a significant degeneration of apical IHCs in the 17–19 mm region. OHCs in this area appeared near normal and other cochlear regions displayed the typical degeneration pattern in the basal and middle turns for this group.

3) Severe hair cell loss. Two animals G 23 and G 34 (Fig. 7). All the OHCs were missing except the apical 17–19 mm region where some of them were present in the second and third row. The IHCs had also nearly totally disappeared. The organ of Corti collapsed in some places in the basal and second coils but pillar cells generally remained in the upper coils in spite of a complete disappearance of sensory elements in that region of the cochlea.

2) Spotty degeneration distributed over the whole cochlea (less than 10 % missing sensory cells in each millimetre) Five animals G 10 G 12, G 14 G 15 and G 16 (Fig 2)
3) Moderate degeneration of the OHCs. Nine animals belonged to this group G 1 G 4 G 5 G 7 G 8 G 9 G 17, G 18 and G 19 The most severe changes were usually seen in two areas in the hook region (round window area) and in the upper basal coil. The extent of injury varied in this group from about 50 % loss of the first row of the OHCs to an almost total loss of the OHCs in the regions named. The average loss of the OHCs of this group is seen in Fig. 3

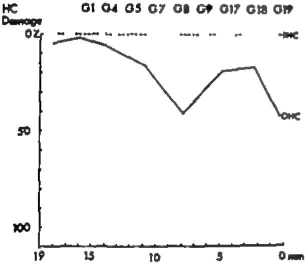

Fig. 3. Extent of mean OHC damage in 9 guinea-pigs treated with gentamicin 50 mg/kg for from 14 to 29 days as determined from the average percentage per millimetre of degenerated OHCs in each examined segment along the organ of Corti. The areas most vulnerable to degeneration are the hook region and the upper part of the basal coil. The IHCs were intact.

3) Gentamicin given 100 mg/kg for from 9 to 21 days, 18 animals.
Characteristic of this group was a great difference in damage between the three subgroups of animals.
1) Slight or no damage, six animals G 22, GA 2 GA 3 GA 4 GA 12 and GA 13 One animal, G 22, (Fig. 4) although given this dose for 21 days, showed changes similar to those often observed in the former group treated with 50 mg/kg for a shorter period of time. The rest of this group were treated for 9 or 10 days and decapitated on the day of the last injection. They displayed only a subtle loss of the OHCs distributed over the entire cochlea.
2) Moderately severe degeneration with complete loss of the OHCs in the basal half of the cochlea and varying damage to the IHCs. This group included 10 animals G 21 G 24 G 26 G 28 G 33 G 35 GA 6 GA 8 GA 14 and GA 16. The damage pattern of the OHCs (Fig. 5) was rather uniform starting basally as a complete loss of the cells

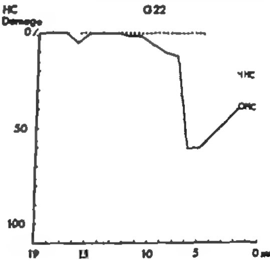

Fig. 4 Extent of hair cell damage in guinea-pig, G 22, given gentamicin 100 mg/kg for 21 days. Despite the large dosage damage was moderate.

in all three outer rows. Collapsed hair cells were replaced by the phalangeal processes of the supporting cells, thus the reticular membrane was still intact. The first hair cells to appear along the basilar membrane were always in the third row these being the most resistant to ototoxic damage. They appeared on the average at the 10 mm level The second row appeared generally 1 mm higher and finally the cells of the first row commonly remained

loss of the OHCs and of the IHCs are presented, these animals displayed severe degeneration of the OHCs. The IHCs were also severely injured in varying degrees. The peculiar capacity of neomycin to produce apical IHC damage was seen in most of these animals.

Electron microscopy

Electron microscopy (EM) often revealed early degenerative changes in the sensory cells while these still appeared normal under a light microscope. There were considerable differences in EM findings between animals decapitated a few days after the last injection and animals which survived one month or more after cessation of treatment. Thus the latter group displayed fewer ultrastructural changes, and the degeneration detected by a light microscope coincided closely with EM-findings. There were no noteworthy ultrastructural differences in animals treated with gentamicin, kanamycin or neomycin provided the pattern of degeneration was similar

In animals with severe OHC degeneration in the basal coil early ultrastructural changes were usually seen in OHCs throughout the cochlea. The earliest changes included an increase in dark bodies unde the cuticular plate. Some of these particles were spherical with variable elec tron density Others were lamellated and some of them were undoubtedly degenerated mitochondria, some were apparently lysosomes. In some cells a fibrous material appeared in the supranuclear part of the cell (Fig. 18)

The regular arrangement of fenestrated membranes along the sides of the cell was often disrupted in the early stage of degeneration. These membranes appeared disarranged in the cytoplasm and showed areas of condensation and rarefaction along the cell membrane. Such irregularities can normally be found in apical areas of the cochlea, but usually not in the lower turns.

A decrease in the ribosome content of the cell was a later finding often coinciding with a widening of interspaces between the layers of the fenestrated membranes along the sides of the OHCs. Vacuolization near the sides of the cells was noted and at the same time an increased number of vesicle granules appeared in the cytoplasm (and in some cells in the nucleus) Later the plasma membrane ruptured at several sites and the cell underwent a disintegration leaving the debris of the mitochondria and remnants of the vesicular component of the cytoplasm at the site of the hair cell in the fluid of Nuel's space. (Fig. 19).

A disorganization of the hair pattern was observed in later stages of degeneration and it was remarkable how well preserved the cuticular plate and the hairs might be in a cell with advanced disintegration in the lower parts of the cell. The IHCs were often even electron microscopically well preserved in areas where the OHCs had completely disappeared. Typical early signs of degeneration in these cells were the appearance of dark inclusion bodies and small vesicle granules in the subcuticular area, slight irregularities in the hair-bearing ends of some cells and nuclear pyknosis in some cells. (Fig. 20)

In some animals decapitated soon after the last injection, profound swellings below the IHCs were observed. These formations were identified as swollen afferent nerve endings and dendrites (Fig. 21) This finding has not been reported earlier after ototoxic drugs. That most of the swellings observed in our animals really are afferent nerve endings can be seen in the electron micrograph where a synaptic bar can be identified on the presynaptic side. Sometimes early degenerative changes were also observed in other nervous elements, such as the myelinated nerve fibers of the osseous spiral lamina and the spiral ganglion cells. The sequence of degeneration of the nerves has, however been analysed in a separate paper and will not be presented here.

The scanning electron microscope is a useful tool for illustration of the surface anatomy of the organ of Corti. Sometimes we observed a disarrangement of the sensory hairs of the IHCs at an early stage of degeneration. Since the stereocilia and the cuticular plate can be well preserved even in severe hair cell injury scanning electron microscopy is useful only in advanced stages of degeneration (Fig. 22)

ance in membrane permeability These changes were seen constantly immediately after exposure to noise but no longer on the following day (Spoendlin, 1971b) We were able to see the swellings of nerve endings in some cases a week or more after the last injection of the drug. Similar swellings have also been demonstrated by Wersäll et al. (1965) as early postmortem changes and can thus be difficult to distinguish from those caused by a delayed or defective fixation. For further discussion of the neuronal elements and their behaviour in the intoxicated animals, the reader is referred to a separately published paper (Ylikoski et al. 1974)

The degeneration pattern produced conforms fairly well with earlier reports indicating that the initial damage is in the basal coil, and the OHCs are the most susceptible to damage (Ruedi et al., 1953 Hawkins & Lurie 1953 Olivieri & Rossi, 1958 Hawkins, 1959 Ward & Fernandez, 1961 Beck & Krahl, 1962, Hawkins & Engström, 1964 Kohonen, 1965 Lundquist & Wersäll, 1967) The OHC loss almost constantly preceded the degeneration of the IHCs and the supporting structures. The pillar cells and the IHCs on the other hand, degenerated in a similar pattern in the basal part of the cochlea. In the upper coils the pillars were consistently well preserved even when hair cells had completely disappeared.

Although the general pattern of damage conformed well with earlier studies, there are some factors to which more attention should be paid because they are of great importance in the development and course of the damage. These factors are

1) the great individual variations in susceptibility to ototoxic drugs
2) differences in damage pattern after various antibiotics
3) the delayed effect of these basic aminoglycoside antibiotics, which makes the survival time important.

1) It was postulated by Hawkins (1967) that in experimental pathology studies ototoxic antibiotics can be used to produce experimental lesions and that it is possible to quantify the degree of injury in terms of dosage and length of treatment.

As has been shown in this paper however there are great variations in individual susceptibility to these antibiotics, thus general conclusions can be made only when a very large number of animals are used. These large individual differences are illustrated by examples in the following figures. In Fig. 12 and Fig. 13 diagrams of percentages of OHC loss and IHC loss are presented for four animals (K 1 K 3 K 6 and K 4) which all were given 300 mg/kg kanamycin for 11 or 12 days. Survival time was in all cases less than 4 days. The first two (K 1 and K 6) exhibit a moderate OHC damage in the basal part of the cochlea but the latter two (K 3 and K 4) have remaining OHCs only in the apical turn.

Fig. 23 demonstrates the average cochleogram for N 3 and for N 10. The dose of neomycin (250 mg/kg) and the duration of treatment (7 days) were equal for both of these animals and both of them survived more than 5 weeks after the last injection. However the former (N 3) experienced only moderate degeneration of cochlear sensory cells compared with the latter (N 10) which had only a few preserved hair cells left in the apical part of the cochlea.

Figs. 7 and 4 demonstrate hair cell pathology in animals G 23 and G 22. The former was treated with 100 mg/kg gentamicin for 16 days, the latter with the same dose for 21 days. As can be seen, the degeneration of sensory cells is severe in the cochlea of G 23 but only moderate in that of G 22

2) The differences in action of various ototoxic antibiotics yields somewhat different patterns of degeneration. As stated previously by Lindsay et al. (1960) in a human case, and by Kohonen (1965) in guinea-pigs, neomycin exhibits a great affinity for the IHCs of the apex. Kohonen postulated that the degeneration of the IHCs starts in the apex and progresses towards the base

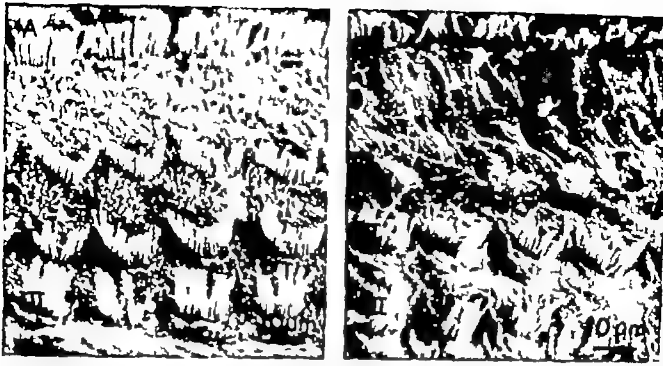

Fig. 22. Scanning electron micrographs of the cochlea of A) a normal guinea-pig and B) a guinea-pig treated with neomycin. The sensory hairs and cuticular plate generally degenerate after the other parts of the cell have disintegrated. In B the cells of the first row of the OHCs have collapsed and the sensory hairs of the other two rows, as well as of the IHCs, are distorted.

DISCUSSION

It seems justified to assess the degree of damage to the organ of Corti by counting the missing and preserved hair cells since apparently the earliest degenerative changes after ototoxic antibiotics take place in the sensory cells (Wersäll 1959 Hawkins, 1959 Friedmann & Bird 1961 Wersäll & Hawkins 1962 Farkashidy et al. 1963 Duvall & Wersäll, 1964 Hawkins & Engström 1964 Lundquist & Wersäll, 1966, 1967)

Kellerhals et al (1967) found after intratympanic administration of kanamycin early toxic changes independent of hair cell degeneration in the first order neurone in the spiral ganglion Hawkins and Johnsson (1968) reported that kanamycin induced early degenerative changes in cells in the outer sulcus and the spiral limbus.

In our study the first degenerative changes were generally detected in the sensory cells especially in the first row of the OHCs in the basal coil. However in a few cases there was slight early damage in some neuronal elements, some spiral ganglion cells and some myelinated nerve fibres of the spiral lamina. In some animals afferent nerve endings and dendrites below the IHCs were swollen These findings confirm the suggestion of Kellerhals et al. (1967) that in addition to the secondary neural degeneration after ototoxic end organ injury a primary neural degeneration might appear which starts at the same time as changes in the neuroepithelium

The swellings of the nerve terminals below IHCs can be reversible and could thus be thought to serve as an explanation for the temporary threshold shifts after both ototoxic drugs and noise exposure Similar swellings were demonstrated by Beagley (1965) and Spoendlin (1971b) after acoustic trauma and by Spoendlin (1969b) after severe ischemia. Beagley interpreted these swellings as swollen supporting cells and Spoendlin identified them as swollen afferent dendrites, and he regarded these changes as the consequence of a disturb-

ance in membrane permeability. These changes were seen constantly immediately after exposure to noise but no longer on the following day (Spoendlin, 1971b). We were able to see the swellings of nerve endings in some cases a week or more after the last injection of the drug. Similar swellings have also been demonstrated by Wersäll et al. (1965) as early postmortem changes and can thus be difficult to distinguish from those caused by a delayed or defective fixation. For further discussion of the neuronal elements and their behaviour in the intoxicated animals, the reader is referred to a separately published paper (Ylikoski et al. 1974).

The degeneration pattern produced conforms fairly well with earlier reports indicating that the initial damage is in the basal coil, and the OHCs are the most susceptible to damage (Ruedi et al., 1953, Hawkins & Lurie 1953, Olivieri & Rossi, 1958, Hawkins, 1959, Ward & Fernandez, 1961, Beck & Krahl, 1962, Hawkins & Engström 1964, Kohonen, 1965, Lundquist & Wersäll, 1967). The OHC loss almost constantly preceded the degeneration of the IHCs and the supporting structures. The pillar cells and the IHCs on the other hand degenerated in a similar pattern in the basal part of the cochlea. In the upper coils the pillars were consistently well preserved even when hair cells had completely disappeared.

Although the general pattern of damage conformed well with earlier studies, there are some factors to which more attention should be paid because they are of great importance in the development and course of the damage. These factors are

1) the great individual variations in susceptibility to ototoxic drugs
2) differences in damage pattern after various antibiotics
3) the delayed effect of these basic aminoglycoside antibiotics, which makes the survival time important.

1) It was postulated by Hawkins (1967) that in experimental pathology studies ototoxic antibiotics can be used to produce experimental lesions and that it is possible to quantify the degree of injury in terms of dosage and length of treatment.

As has been shown in this paper, however, there are great variations in individual susceptibility to these antibiotics, thus general conclusions can be made only when a very large number of animals are used. These large individual differences are illustrated by examples in the following figures. In Fig. 12 and Fig. 13 diagrams of percentages of OHC loss and IHC loss are presented for four animals (K 1, K 3, K 6 and K 4) which all were given 300 mg/kg kanamycin for 11 or 12 days. Survival time was in all cases less than 4 days. The first two (K 1 and K 6) exhibit a moderate OHC damage in the basal part of the cochlea but the latter two (K 3 and K 4) have remaining OHCs only in the apical turn.

Fig. 23 demonstrates the average cochleogram for N 3 and for N 10. The dose of neomycin (250 mg/kg) and the duration of treatment (7 days) were equal for both of these animals and both of them survived more than 5 weeks after the last injection. However the former (N 3) experienced only moderate degeneration of cochlear sensory cells compared with the latter (N 10) which had only a few preserved hair cells left in the apical part of the cochlea.

Figs. 7 and 4 demonstrate hair cell pathology in animals G 23 and G 22. The former was treated with 100 mg/kg gentamicin for 16 days, the latter with the same dose for 21 days. As can be seen, the degeneration of sensory cells is severe in the cochlea of G 23 but only moderate in that of G 22.

2) The differences in action of various ototoxic antibiotics yields somewhat different patterns of degeneration. As stated previously by Lindsay et al. (1960) in a human case and by Kohonen (1965) in guinea-pigs, neomycin exhibits a great affinity for the IHCs of the apex. Kohonen postulated that the degeneration of the IHCs starts in the apex and progresses towards the base

and that this kind of damage pattern is seen in animals treated with neomycin and kanamycin In our results there is only 1 animal (K 3) treated with kana mycin which displays more extensive IHC damage in the apex than in the base of the cochlea. This kind of damage pattern was never found in animals treated with gentamicin, but one G 13 demonstrated a similar IHC degeneration both apically and basally *On the other hand* we had a great

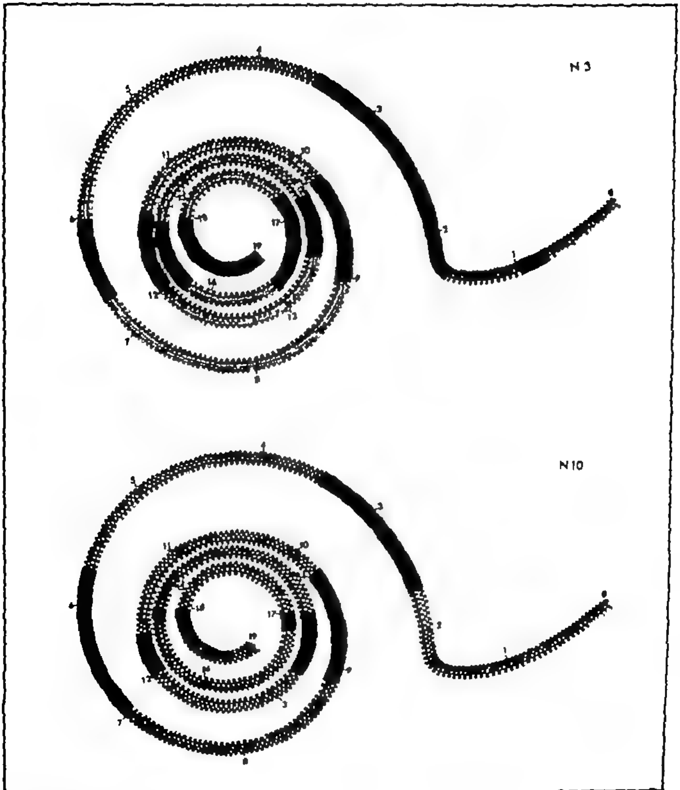

Fig. 23 Averaged cochleogram of 2 guinea-pigs treated with neomycin 250 mg/kg for 7 days. Both animals survived for longer than 5 weeks. Considerable variation in the extent of damage is apparent. Open circles normal cell groups. Filled circles damaged cell groups.

number of animals treated with kanamycin and gentamicin which experienced extensive IHC damage basally whereas the IHCs were nearly intact in the apex. After neomycin administration, however the degeneration of the IHCs in the apex was an almost constant finding. In some cases using neomycin it was possible to create a complete apical IHC loss when about 50 % of the OHCs were still present. In one animal (N 4) the cochlea was devoid of IHCs in the apical 2 mm area although 75 % of the OHCs were present there.

In the early stage of degeneration there was a scattered loss of the first row of OHCs relatively randomly distributed throughout the entire cochlea. This mild damage was independent of the antibiotic used. When the injury was somewhat greater and larger groups of adjacent OHCs were observed to be missing, the localisation of damage depended on the antibiotic. Neomycin seemed to destroy initially the OHCs of the extreme basal area, leaving other parts of the cochlea intact at the early stage Kanamycin and gentamicin, on the other hand, first destroyed the OHCs simultaneously in the hook area and in the upper basal coil while the area between was relatively well preserved. The OHCs of the hook were usually more severely affected and the degeneration was milder in the upper basal coil. When the damage progressed the OHCs in the basal coil all rapidly disappeared while the spiral spread of injury was slower towards the apex. There were also some differences in advanced stages of degeneration. Both kanamycin and neomycin destroyed the first row of OHCs much farther up than gentamicin. This is illustrated by a comparison of animals treated with gentamicin and kanamycin which displayed damage where the OHCs were missing in the lower half of the cochlea (Figs. 5 and 9) and the distance between the point where the third row of OHCs appeared and the point where the first row of OHCs appeared was in gentamicin animals averaged 3 mm in the kanamycin group 8 mm. This demonstrates that the damage pattern after gentamicin does not follow the distribution of the large, granulated nerve endings along the cochlea as has been earlier suggested in animals intoxicated with neomycin and kanamycin (Kohonen, 1965)

3) All the ototoxic aminoglycoside antibiotics accumulate in the fluids of the inner ear (Stupp et al. 1965 Voldrich, 1965 Stupp, 1970 Ylikoski et al. 1974) This capacity does, however vary somewhat depending on the antibiotic. From this it follows that these antibiotics exert their damaging action in different ways. Neomycin presumably has the strongest capacity to concentrate in the endolymph and perilymph because of its slow elimination rate (Ylikoski et al. 1974) and the degenerative changes produced by it can progress weeks or even months after the cessation of treatment (Leach, 1962) This makes the time elapsed from the start of treatment very important. This is illustrated in Fig. 24 where cochlear charts for NA 3 and N 14 are presented. Both of these animals were given neomycin 250 mg/kg. The duration of treatment was 8 days for NA 3 and it was sacrificed on the 8th day N 14 was treated for only 5 days and was decapitated 10 months later. Under a light microscope the organ of Corti of NA 3 appeared almost normal, except in the basal 3 mm area where the OHCs had suffered damage. It had almost totally disappeared in N 14 Although even electron microscopy revealed only the earliest signs of degeneration in the hair cells of NA 3 outside the damaged basal area, it is probable that if the animal had survived at least 1 month, it would have exhibited a pronounced damage of the hair cells as did the other animal treated with the same dose. Kanamycin and gentamicin had a milder delayed effect than neomycin but it is clear that if one

intends to quantify the degree of damage after ototoxic antibiotics in terms of dosage the survival time must be at least 3 or 4 weeks.

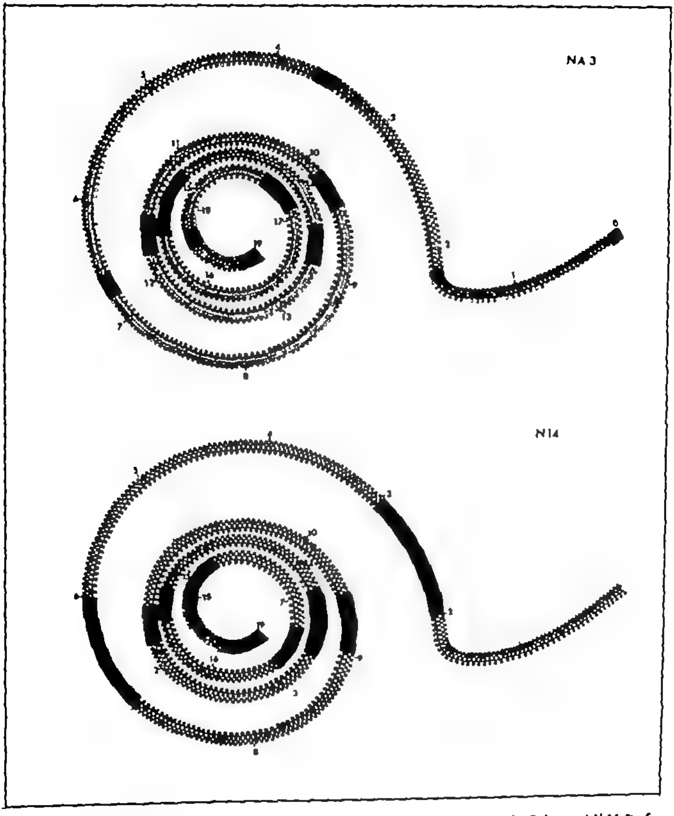

Fig. 24. Averaged cochleogram of 2 guinea-pigs treated with neomycin 250 mg/kg. NA 3 for 8 days and N 14 for 5 days. NA 3 survived 0 days, N 14 survived 10 months.

DEGENERATION OF NEURAL ELEMENTS IN THE COCHLEA OF THE GUINEA-PIG AFTER DAMAGE TO THE ORGAN OF CORTI BY OTOTOXIC ANTIBIOTICS

J Ylikoski, J Wersäll, B Björkroth

It was found as early as 1907 by Wittmaack that noise induced destruction of the organ of Corti and that this destruc tion was accompanied by neural degener ation in the osseous spiral lamina and in the spiral ganglion. Hoessli observed five years later that inner hair cells (IHCs) were more resistant to acoustic trauma than were outer hair cells (OHCs) and that the neural cells in the spiral ganglion degenerated first when IHCs were destroyed

In the earliest reports on the destruction of the organ of Corti induced by the administration of ototoxic antibiotics, such destruction was observed to be accompanied by the degeneration of corresponding neural elements (Ruedi et al., 1953 Riskaer et al., 1956 Olivieri & Rossi, 1958 Hawkins, 1959 Friedmann & Bird, 1961 Catalano et al., 1961) Several investigators, on the other hand have noticed no neural degeneration after the administration of such antibiotics apparently either because the degeneration they induced was limited to the OHCs and left the IHCs intact or the survival times of the experimental animals were too short for a full evaluation to be possible (Hawkins & Lurie 1953 Ward & Fernandez, 1961 Mesolella & Costa, 1960 Ardouin et al 1963 Farkashidy et al. 1963) In their investigation Farkashidy et al. were also able to see well-preserved outer spiral bundles (OSBs) and inner spiral bundles (ISBs) in specimens in which the OHCs had been destroyed. Engström et al. (1966) on the basis of the staining technique of Maillet concluded that the radiating fibres together with their nerve endings constituted a system especially sensitive to ototoxic antibiotics, whereas the long, spirally-running fibres of the ISB tunnel spiral b (TSB) and OSBs were less vulnerabl survived much longer

In his studies in the cat Schul (1953b) observed that in experim produced lesions the decrease in h population usually greatly exceed loss of spiral ganglion cells. The de ative changes in the spiral gangli peared to parallel more closely the of the injury suffered by the sup cells, particularly the pillar cells. findings have also been reported by (1965) and by Spoendlin (1966)

The intimate relationship between degeneration and the degeneration supporting cells was reported in r Hawkins & Johnsson (1968) by Jo & Hawkins (1972) and by Lawr Johnsson (1973) and in monkeys b bins et al. (1969)

On the other hand Kellerhals (1967) noted in guinea-pigs a clea lation between the degeneration c and ganglion cells. Similar findin reported by Bredberg (1968) who study on the human cochlea, observ a complete loss of sensory cells in segment was invariably accompanie complete loss of nerve fibres in a sponding segment of the osseou lamina. Total or extensive loss of OH never associated with any noticeab faction of nerve fibres in the corresp sector of the osseous spiral lamin vided that the IHCs remained intact.

In a recent investigation in the pig, Spoendlin (1973) observed generation of nerve fibres after a le the organ of Corti had been indu acoustic trauma and found that a

ible to observe sensory cells to be completely destroyed while the pillar cells were almost intact

3) The OHCs were totally missing but the IHCs were well preserved In these instances the pillar cells and other supporting structures were invariably present and virtually intact
4) The OHCs were partially damaged with an average of 30 % missing. In such cases the IHCs and pillar cells were always intact except in the apex of neomycin-treated animals
5) The IHCs were completely destroyed in the apex while 50–75 % of the OHCs were preserved An example of this kind of degeneration was seen in animals treated with neomycin.

RESULTS

1) When the *organ of Corti* was *completely destroyed* (Fig 1B) the spiral ganglion still contained some ganglion cells. The number of neurons in the intraganglionic spiral bundle was clearly reduced and in the osseous spiral lamina only a few myelinated and unmyelinated nerve fibres remained The quantitative estimate of the remaining nervous elements provided the results shown in Table 1 The number of surviving spiral ganglion cells was unexpectedly high more than 1/3 of the *normal number in three out of four* specimens studied In only one specimen was their number less than 1/3 of normal

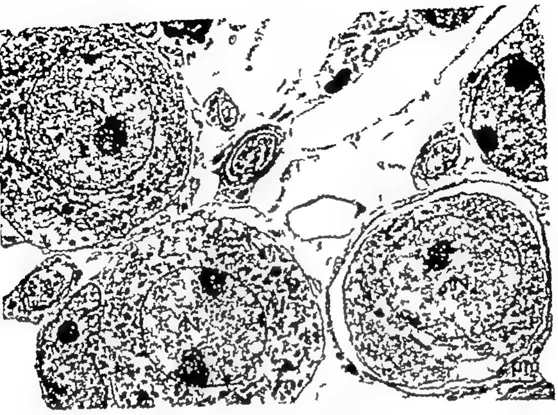

Fig. 2. Low magnification electron micrograph of th spiral ganglion from specimen in which th organ of Corti was completely destroyed by neomycin (N 14/5 mm). The cells are well preserved, displaying only slight abnormalities such as an increase in the number and size of multivesicular bodies and pigment granules (arrows), and vesiculation of the nucleoli (N). Two of these cells are unmyelinated.

The intraganglionic spiral bundle was well preserved in two specimens in which more than 2/3 of the fibres were still present. In two other specimens the rarefaction was somewhat greater with between 1/3 and 2/3 of the neurons surviving. The number of myelinated nerve fibres in the osseous spiral lamina was extensively reduced in all specimens examined. The number of remaining fibres varied between 214 and 520 per millimetre. The myelinated fibres were usually easy to follow from the spiral ganglion to the habenula perforata but not beyond and no identifiable nerve fibres were detected within the remnants of the totally collapsed organ of Corti.

Althought the surviving nerve fibres were usually ultrastructurally normal, electron microscopy sometimes revealed degenerative changes that were not observable by light microscopy. The surviving spiral ganglion cells of animals belonging to this group appeared even finestructurally almost normal. Slight abnormalities consisted of an increase in the number and size of multivesicular bodies and pigment granules in the perikaryon. Some cells also displayed an increase in the prominence and distention of the Golgi vacuoles, a swelling of the mitochondria and an expansion of the cisternae of the granular endoplasmic reticulum. The nuclei of such cells contained nucleoli that often had a vesiculated appearance and a large amount of nucleolus-enriched chromatin. (Fig. 2)

The relative number of unmyelinated filamentous type II ganglion cells was high in animal N 14 in which about

Fig. 3. Low magnification electron micrograph of the spiral ganglion from a specimen in which all the sensory cells had degenerated but in which the pillar cells had survived (K 14/9 mm). Signs of degeneration in these spiral ganglion cells are the distortion of Golgi vacuoles, the expansion of the cisternae of the granular endoplasmic reticulum (arrows), and the movement of Nissl substance nearer the nucleus.

the last injection were relatively short. In one, K 4 that was decapitated on the 16th day after the beginning of treatment, light microscopic countings of the nerve fibres in the ganglion and osseous spiral lamina were the same as in normal animals. The other, K 15 was decapitated on the 47th day after the start of treatment. In the quantitat ive analysis of this specimen there was only a moderate reduction in the number of nerve fibres in the spiral ganglion and lamina. Because these two specimens varied even ultrastructurally from the rest of this group they are mentioned separately

Electron microscopy revealed a picture of the cells in the spiral ganglion and spiral lamina that resembled that of the foregoing group In some spiral ganglion cells the mitochondria were swollen and their cristae were disarranged. In addition the number and size of multivesicular bodies, dark bodies and Golgi vacuoles had increased. Some cells displayed large vacuoles and their Nissl substance had moved nearer the nucleus leaving the cytoplasm adjacent to the cell membrane vacant and thus less electron dense. (Fig. 3) Occasional cells exhibited extensive degeneration with severe vacuolization in karyoplasm that had shrunk. The majority of the surviving ganglion cells had a thin myelin sheath and resembled the regular type I ganglion cells. Approximately 25 % of the ganglion cells were unmyelinated.

About 30 % of the surviving axons of the intraganglionic spiral bundle and the osseous spiral lamina showed ultrastructural degenerative changes similar

Table 2. *Quantitative analysis of remaining neurons in those specimens in which all the sensory cells were destroyed but in which the supporting cells and the tunnel of Corti survived. ISB = inner spiral bundle, TSB = tunnel spiral bundle, OSB = outer spiral bundle.*

50 % of the surviving ganglion cells were unmyelinated in both the sections studied In two other animals all the preserved ganglion cells had a myelin sheath. The sheath was normally thin but these myelinated ganglion cells were otherwise similar to the regular type I ganglion cells. The subtle abnormalities observed in this group of animals randomly affected both myelinated and unmyelinated ganglion cells.

More than 50 % of the surviving nerve fibres in the intraganglionic spiral bundle appeared to be ultrastructurally normal The rest of the axons exhibited some greater or lesser degenerative change, most often a deformation of the myelin sheath. The fibres had then often lost their typical roundoval con figuration and had been transformed into collapsed figures that consisted only of a narrow core containing a greatly reduced amount of axoplasm The lamellated construction of the myelin sheath was, however generally well preserved. The axoplasm of many nerve fibres displayed diminished electron density and the number of neurofilaments and microtubules was often reduced Sometimes the axoplasm had become dark and held dark inclusion bodies and vacuoles that appeared to be enlarged agranular endoplasmic reticulum Unmyelinated nerve fibres seemed to be less affected by such degenerative changes than myelinated fibres.

The myelinated axons in the osseous *spiral lamina exhibited ultarastructural* changes similar in character and frequency to those seen in the intraganglionic spiral bundle. A characteristic abnormality was the collapse of the otherwise normal myelin sheath as a result of the diminution of axoplasm

2) When the *tunnel of Corti was preserved* (Fig. 1C) although often tilted, and *all the hair cells had disappeared,* neural damage in the spiral ganglion and in the osseous spiral lamina was similar to that observed when the organ of Corti had been completely destroyed (Table 2) Approximately 1/3 of the spiral ganglion cells remained. The *number of myelinated neurons* in the intraganglionic spiral bundle was reduced to about 1/3 to 2/3 of the normal number The osseous spiral lamina contained between 174 and 535 myelinated fibres per millimetre In these specimens it was clearly seen that when occasional IHCs had survived the density of nerve fibres in the osseous spiral lamina was also greater in that area.

This group contained specimens from two animals whose survival times after

Fig. 4. Low magnification electron micrograph of the *osseous spiral lamina from a specimen in which all the* sensory cells were destroyed but in which the supporting cells had survived (G 34/11 mm). Only about 10% of the myelinated nerve fibres in this section remained and *some of these exhibited* degenerative changes such as a collapsed myelin sheath and a reduced amount of axoplasm (arrow).

to those described in the fibres of the foregoing group (Fig. 4).

Some unmyelinated dendrites within *the organ of Corti were still present in* two sections (G 34) but the number of *tunnel-crossing fibres had been reduced* to 1/10 of normal. The spirally running *fibres in these sections were somewhat* better preserved although also clearly diminished in number. The outer spiral fibres moreover appeared better preserved than either the tunnel or the inner spiral fibres.

Sections from two animals with relatively *short survival times* revealed more neurons than other specimens in this group. They appeared to be undergoing degeneration and abnormalities, manifested as degenerative changes in the karyoplasm similar to those mentioned in the first group were frequently observed (Fig. 5). In addition the myelin sheath was often disarranged and vacuolized at a stage when the axoplasm still contained a relatively *intact complement of neuro*-filaments and microtubuli. In the organ *of Corti both radial and spiral dendrites* were observed to have undergone degeneration. The neurilemma was often swollen and enclosed axoplasm that lacked neurofilaments; sometimes the neurilemma had ruptured releasing its contents into the fluid space.

3) In many cochleas *the outer hair cells* were completely *destroyed* (Fig. 1D) in *the lower half of the cochlea while the* set of *inner hair cells* was still *essentially intact*. In such specimens light microscopy revealed a normal density of nerve fibres in the osseous spiral lamina and in the spiral ganglion as well as the normal number of neural elements in these locations (Table 3).

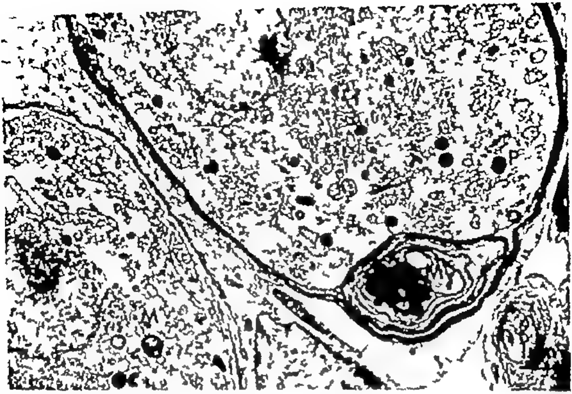

Fig. 5 Electron micrograph of the spiral ganglion from specimen in which all the sensory cells were destroyed by kanamycin (K 4/9 sem). Because survival time had been short (4 days), the number of neurons was still nearly normal, but many of them displayed early degenerative changes such as an increase in the number and prominence of pigment granules (P) and multivesicular bodies (M), and the formation of myelin figures (My) at the cell poles.

The spiral ganglion cells in these specimens generally appeared normal even by electron microscopy. Some cells displayed degenerative changes such as vacuolization of the cytoplasm with an increase in the prominence and number

of Golgi zones, the formation of whirls of myelin lamellae in the cellular poles and finally disruption and fragmentation of the myelin sheaths.

The myelinated and unmyelinated nerve fibres within the intraganglionic spi-

Fig. 7. High magnification electron micrograph of the tunnel of Corti from [illegible] specimen in which degeneration was similar to that as seen in Fig. 6. The number and state of both upper (U) and basilar (B) tunnel-crossing fibres appears normal. BM, basilar membrane; P, pillar foot.

ral bundle and spiral lamina usually appeared to be finestructurally normal. In occasional specimens the axoplasm had become increasingly vacuolated and darkened and myelin figures had formed.

The number and state of the unmyelinated dendrites in the organ of Corti in this group of specimens varied somewhat. In one section (N 13/9 mm) only a few fibres were present in the tunnel of Corti and the feet of the outer pillars were severely swollen. The spiral bundles were better preserved although slightly diminished in number. In another neomycin-treated animal (N 6) the number of both the upper efferent fibres and the basilar fibres appeared reduced in three separate sections (5, 6 and 9 mm). The spiral fibres were also reduced in number in the most basal section of this cochlea. In two genta-

micin-treated animals (G 21 and G 24) the spiral bundles appeared normal except in one section of the former animal (G 21/5,5 mm) in which the number of fibres in the ISB was clearly diminished. Tunnel-crossing fibres appeared well preserved. In G 24 there was an unusually high number of *efferent tunnel-crossing fibres in both* sections studied (Fig. 6 and Fig. 7). In both neomycin-treated animals in this group the surviving fibres in the tunnel frequently displayed signs of degeneration. These axons were swollen, their neurofilaments and microtubules were strikingly rarefied and destroyed, and their mitochondria were sometimes distended.

4) *A partial loss of outer hair cells* alone was never associated with either rarefaction or loss of radial spiral nerve fibres in the corresponding sector of the *spiral ganglion or osseous spiral* lamina (Table 4). The unmyelinated *dendrites within the organ of Corti also* remained unaltered both in number and appearance. In one specimen (G 21/13 mm) swollen afferent nerve endings were observed below the IHCs, a region that appeared normal in two sections from the lower parts of the same cochlea (9 mm and 5,5 mm). That some such swellings were in fact afferent nerve endings is evident from the Fig. 8 in which the synaptic bar is identifiable on the presynaptic side.

5) *A complete loss of inner hair cells* in a region of the organ of Corti where *outer hair cells* had only *partially disappeared* (Fig. 1E) was usually observed *in the apical part of the cochlea* of the animals treated with neomycin. These regions displayed an unexpectedly well preserved pattern of nerve fibres in the osseous spiral lamina. In fact, in two specimens the number of myelinated laminar fibres was essentially normal (Table 5). The spiral ganglion was not studied at this level. The unmyelinated dendrites in the organ of Corti,

both spiral and radial, appeared quantitatively as well as qualitatively normal. A spatial differentiation between upper tunnel-crossing fibres and basilar fibres was not possible at this 18 mm level

DISCUSSION

1) *Effect of ototoxic aminoglycoside antibiotics on the cochlea*

Abundant data exist about the effect of ototoxic antibiotics on the sensory cells and neurons of the cochlea. Evidence points to a distinct spatial pattern of degeneration among the hair cells. Neural elements had been stated to degenerate almost simultaneously with hair cells in a distinct sequential pattern that parallel that of the hair cells but that lags slightly behind (Kohonen, 1965) Electron microscopic studies have shown that neural elements are still intact when obvious

micin-treated animals (G 21 and G 24) the spiral bundles appeared normal except in one section of the former animal (G 21/5 5 mm) in which the number of fibres in the ISB was clearly diminished *Tunnel-crossing fibres* appeared well preserved In G 24 there was an unusually high number of efferent tunnel-crossing fibres in both sections studied (Fig 6 and Fig 7) In both neomycin-treated animals in this group the surviving fibres in the tunnel frequently displayed signs of degeneration. These axons were swollen their *neurofilaments and microtubules* were strikingly rarefied and destroyed and their mitochondria were sometimes distended

4) *A partial loss of outer hair cells* alone was never associated with either rarefaction or loss of *radial spiral nerve* fibres in the corresponding sector of the spiral ganglion or osseous spiral lamina (Table 4) The unmyelinated dendrites within the organ of Corti also remained unaltered both in number *and appearance. In one specimen* (G 21/13 mm) swollen afferent nerve endings were observed below the IHCs, a region that appeared normal in two sections from the lower parts of the same cochlea (9 mm and 5,5 mm) That some such swellings were, in fact afferent nerve endings is evident from the Fig. 8 in which the synaptic bar is identifiable on the presynaptic side.

5) A *complete loss of inner hair cells* in a region of the organ of Corti *where outer hair cells* had only *partially disappeared (Fig. 1E) was usually* observed in the apical part of the cochlea *of the animals treated with neomycin.* These regions displayed an unexpectedly well preserved pattern of nerve fibres in the osseous spiral lamina. In fact, in two specimens the number of myelinated laminar fibres was essentially normal (Table 5) The spiral ganglion was not studied at this level The unmyelinated dendrites in the organ of Corti,

degeneration after the end organ has been damaged.

To distinguish between the efferent and afferent fibres that cross the tunnel is extremely difficult in the guinea-pig. Although the efferent fibres to the OHCs usually cross the tunnel of Corti at a higher level than their afferent counterparts, there is often an intermingling of efferents that run at a relatively low level and afferents that sometimes freely cross the tunnel in the Cortilymph. The distinction we employed in our analysis is, however based on a spatial separation.

The tunnel-crossing fibres were usually well preserved as long as the IHCs and supporting cells were essentially intact. In one section, however these fibres had degenerated severely even though the IHCs were nearly intact and the OHCs were missing but when the feet of the outer pillar cells were markedly swollen. It seems likely therefore that for tunnel-crossing fibres to survive the intact state of supporting cells is important. When these fibres degenerated, moreover both efferent and afferent fibres were randomly affected.

In examining the apical region of the cochlea (18 mm) we made a surprising observation. In spite of the complete loss of IHCs and about a 50 % loss of OHCs, the myelinated fibres in the osseous spiral lamina and the unmyelinated fibres in the organ of Corti were as numerous as in normal control animal. In this region all the tunnel-crossing fibres appeared to be afferent.

1) *Ultrastructural signs of degeneration in the osseous spiral lamina and spiral ganglion*

Only a few electron microscopic studies of the degenerative changes that take place in the spiral ganglion cells after administration of ototoxic antibiotics have been carried out.

Awataguchi et al. (1967) observed, in kanamycin-treated guinea-pigs, degenerative changes that consisted of a dilatation of the endoplasmic reticulum a widening of Golgi vacuoles, swelling of mitochondria whose cristae had become deformed, a decrease in the electron density of the cytoplasmic matrix, swellings of the nuclear membrane and finally vesiculation of the myelin sheath. Unmyelinated ganglion cells were more susceptible to such degenerative changes than were myelinated cells

In their study of guinea-pigs treated with neomycin Friedmann et al. (1966) found that the earlier stages of degeneration affected mitochondria and Nissl substance and that multicystic cytosomes and myelin figures also developed at this time.

Kellerhals et al. (1967) studying the spiral ganglion cells of guinea-pigs treated with kanamycin, observed early degenerative changes in the form of swollen nuclei that often moved towards the periphery of the cell, nucleoli that became enlarged and vacuolated, and Nissl substance that accumulated at the poles of the cell. They also noted the accumulation of cellular organelles near the nuclei, whirlformations of endoplasmic reticulum, swollen nuclei in satellite cells and increased folding of the myelin sheath at the cellular poles. Both unmyelinated and myelinated ganglion cells were similarly affected.

The signs of mild injury that we observed consisted of an increase in the number and size of multivesicular and pigment bodies, a distention of Golgi vacuoles, swelling of mitochondria and an expansion of the cisternae of granular endoplasmic reticulum. The myelin sheath was usually still intact in animals that had survived several months. In more acutely affected animals however it was often deformed, sometimes even disrupted or vacuolized, and in some such severly affected cells whirls of myelin lamellae had accumulated at the poles. Spiral ganglion cells that lacked a myelin sheath were often better preserved than cells encased in myelin.

Ultrastructural changes in the myelinated axons of the spiral ganglion and the osseous spiral lamina induced by ototoxic antibiotics have not been reported previously In the present study manifestations of the early degenerative changes in these neurons were an increased vesicu-

degenerative changes are already noticeable in the hair cells after the administration of *kanamycin* (Lundquist & Wersäll, 1966) neomycin (Friedmann et al 1966 Spoendlin 1970) and gentamicin (Lundquist & Wersäll, 1967)

On the other hand Kellerhals et al (1967) *observed that after intratympanic administration of* kanamycin in guinea-pigs, degenerative changes in the spiral ganglion cells preceded damage to the neurons in the osseous spiral lamina and sometimes *even damage to the hair cells. They con*cluded that the damage suffered by the spiral ganglion is most severe in the apex with severity diminishing towards the base *They claimed furthermore that the* nature of the degenerative process after administration of kanamycin is mixed consisting of both the direct toxic effect on the spiral ganglion cells and the retrograde degeneration that follows destruction of *hair cells.*

In our investigation the earliest degenerative changes usually appeared in the hair cells The spiral ganglion and osseous spiral lamina were invariably normal *by light microscopy when the OHCs* had been partially or completely destroyed and the IHCs were still essentially intact In a few animals, however electron microscopy revealed early signs of *neural degeneration while the correspond* ing hair cells still appeared nearly normal These changes were seen as swellings below *the IHCs, apparently swollen afferent nerve* endings and dendrites. Such swellings were observed in one animal 11 days after the beginning of treatment and in another as long as 43 days after the cessation of treatment. Similar degenerative changes have been reported after ischemia (Spoendlin 1969b) and after acoustic trauma (Beagley 1965 Spoendlin 1971b) Whether such changes are to be interpreted as true pathological *findings or as fixation artefacts* remains to be determined.

2) Relationship between the degeneration of the organ of Corti and of the neural elements

In recent years, transection experiments, mainly the work of Spoendlin (1966 1969 1971a) have greatly contributed to our understanding of the complex nerve supply to the organ of Corti. Spoendlin found that in the cat IHCs have numerically an overwhelmingly *predominant afferent in*nervation and are in fact associated with *about 95 % of the cochlear neurons. Simi*lar conclusions were reached by Morrison et al. (1974) in their study of de-efferentized guinea-pigs and have been corroborated as well in the work of Kellerhals et *al (1967) Bredberg (1968) and Spoendlin* (1973) all of whom observed that a partial or complete loss of OHCs alone was not associated with any rarefaction or loss of *nerve fibres in the osseous spiral lamina or spiral ganglion*

In our quantitative analysis of the myelinated laminar fibres, their number was normal when the OHCs alone had been partially or completely destroyed We *counted in the upper basal coil approxima*tely 2240 fibres per millimetre a number somewhat greater than the 1750 per millimetre reported by Spoendlin (1972) and by Morrison et al (1974) The difference in *our numbers is explained however by the* level at which these counts were made We counted fibres at the level of the inner sulcus whereas Spoendlin and Morrison counted more distally at the habenular level When both OHCs and IHCs are missing the density of nerve cells in the osseous spiral lamina is extensively rarefied provided the animal has survived long enough for the degeneration to have run its course The preservation or destruction of *the pillar cells appeared to have no direct* influence on the degeneration of neurons in *the lamina The degeneration of cells in the* spiral ganglion *was related to hair cell* damage in much the same way as was true of the laminar fibres. OHC loss alone was not associated with any rarefaction of the spiral ganglion cells but when IHCs had disappeared extensive loss of ganglion cells was also apparent The number of myelinated fibres *in the intraganglionic spiral bundle was often reduced in severely dama*ged cochleas. This would mean that some efferent myelinated nerve fibres undergo

degeneration after the end organ has been damaged.

To distinguish between the efferent and afferent fibres that cross the tunnel is extremely difficult in the guinea-pig. Although the efferent fibres to the OHCs usually cross the tunnel of Corti at a higher level than their afferent counterparts, there is often an intermingling of efferents that run at a relatively low level and afferents that sometimes freely cross the tunnel in the Cortilymph. The distinction we employed in our analysis is, however based on a spatial separation.

The tunnel-crossing fibres were usually well preserved as long as the IHCs and supporting cells were essentially intact. 2) *Relationship between the degeneration of the organ of Corti and of the neural elements*

In recent years, transection experiments, mainly the work of Spoendlin (1966 1969 1971a) have greatly contributed to our understanding of the complex nerve supply to the organ of Corti Spoendlin found that, in the cat IHCs have numerically an overwhelmingly predominant afferent innervation and are in fact associated with about 95 % of the cochlear neurons. Similar conclusions were reached by Morrison et al (1974) in their study of de-efferentized guinea-pigs and have been corroborated as well in the work of Kellerhals et al. (1967) Bredberg (1968) and Spoendlin (1973) all of whom observed that a partial or complete loss of OHCs alone was not associated with any rarefaction or loss of nerve fibres in the osseous spiral lamina or spiral ganglion

In our quantitative analysis of the myelinated laminar fibres, their number was normal when the OHCs alone had been partially or completely destroyed We counted in the upper basal coil approximately 2240 fibres per millimetre a number somewhat greater than the 1750 per millimetre reported by Spoendlin (1972) and by Morrison et al (1974) The difference in our numbers is explained however by the level at which these counts were made We counted fibres at the level of the inner sulcus whereas Spoendlin and Morrison counted more distally at the habenular level When both OHCs and IHCs are missing the density of nerve cells in the osseous spiral lamina is extensively rarefied provided the animal has survived long enough for the degeneration to have run its course The preservation or destruction of the pillar cells appeared to have no direct influence on the degeneration of neurons in the lamina. The degeneration of cells in the spiral ganglion was related to hair cell damage in much the same way as was true of the laminar fibres. OHC loss alone was not associated with any rarefaction of the spiral ganglion cells but when IHCs had disappeared extensive loss of ganglion cells was also apparent The number of myelinated fibres in the intraganglionic spiral bundle was often reduced in severely damaged cochleas. This would mean that some efferent myelinated nerve fibres undergo

Kellerhals observed irreversible changes in the ganglion cells of guinea-pigs 10–20 days after intratympanic administration of kanamycin.

We observed some degenerative changes in the radial neurons within the organ of Corti, in the osseous spiral lamina and in the spiral ganglion cells in one animal (K 4) sacrificed 16 days after the beginning of treatment. In another animal (K 15) one that survived 4 weeks, the number of nervous elements was reduced at all of these three levels but the degeneration was not as obviously complete as it was in K 14 an animal that had survived for 64 days. It would appear therefore that it takes no less than one month for the degeneration of nerve fibres in the osseous spiral lamina and in the spiral ganglion to run its course.

lation and occasional darkening of the axoplasm, the appearance of various inclusion bodies in the axoplasm and the formation of myelin figures. At later stages the myelin sheath had often collapsed and the axoplasm which was sometimes both less electron dense than normally and devoid of neurofilaments and tubuli had markedly diminished in quantity

4) The nature of surviving nervous elements

A) Surviving fibres in the osseous spiral lamina

Myelinated laminar fibres consist of afferent neurons of both OHCs and IHCs. According to Spoendlin (1969a) the nerve fibres that supply the IHCs in the cat are far more numerous than those that innervate the OHCs, the ratio being 95:5 It could therefore be expected that after the destruction of all OHCs the number of myelinated fibres would be reduced by 5 % Morrison et al. (1974) estimated the percentage of afferent fibres associated with OHCs to consist of approximately 10–15 % of all myelinated laminar fibres in the guinea-pig. Unfortunately estimates of variations in the number of fibres made with the present technique does not allow for any conclusion related to a variation below about 20 %.

In several cochleas in which the organ of Corti was severely damaged between 10 and 25 % of the fibres in the lamina survived It has been pointed out that a portion of the myelinated laminar fibres belong to the efferent olivocochlear system (Terayama, 1969 1971 Morrison et al 1974) Morrison et al have also shown that these efferent fibres comprise about 25–30 % of all laminar fibres in the guinea-pig. The question of whether the fibres that survived in our study are afferents to type II unmyelinated ganglion cells (Spoendlin 1973) or efferents that have undergone partial degeneration (as did the fibres in the intraganglionic spiral bundle in most specimens) remains to be answered.

B) Surviving spiral ganglion cells

More than 50 % of the preserved spiral ganglion cells in cochleas in which all sensory cells had been destroyed were myelinated. These spiral ganglion cells regularly displayed a relatively thin myelin sheath and could thus be considered to be type III ganglion cells as classified by Spoendlin (1973) although they were in no other way morphologically different from the regular type I ganglion cells. The karyoplasm and nuclei of unmyelinated ganglion cells were usually not appreciably different from that of type I ganglion cells. Their abundance, however raises the question of whether they were true primary unmyelinated cells or cells that had lost their myelin sheath as the result of degeneration.

Rate of neural degeneration

Wallerian or descending degeneration occurring when the axon is interrupted at any point is known to take place quickly and to lead to a complete breakdown of the distal portion of the axon. After transection of the olivocochlear bundle rapid changes of this kind were observed by Iurato (1961) in rats after 16 hours, by Kimura & Wersäll (1962) in the guinea-pig and by Smith & Rasmussen (1963) in the chinchilla after 2–3 days. Spoendlin saw obvious degeneration in the efferent nerve endings in the cat one week after transection and changes had developed fully after 3 weeks.

Retrograde degeneration, another type of degeneration that occurs when the axon is interrupted or the end organ is destroyed affects the proximal portion of the axon Such degeneration is known to occur slowly and is usually incomplete.

We know that degeneration of sensory cells can take place within a few days after the application or introduction of a damaging agent, only scant data exists, however about the rate of neural degeneration when the primary lesion affects the organ of Corti. Lurie et al. (1944) noticed the first degenerative changes in the laminar nerve fibres of the guinea-pig 9 days after exposure to noise whereas degeneration of the ganglion cells did not take place until 3–4 weeks after such exposure.

Kellerhals observed irreversible changes in the ganglion cells of guinea-pigs 10–20 days after intratympanic administration of kanamycin.

We observed some degenerative changes in the radial neurons within the organ of Corti, in the osseous spiral lamina and in the spiral ganglion cells in one animal (K 4) sacrificed 16 days after the beginning of treatment. In another animal (K 15) one that survived 4 weeks, the number of nervous elements was reduced at all of these three levels but the degeneration was not as obviously complete as it was in K 14 an animal that had survived for 64 days. It would appear therefore that it takes no less than one month for the degeneration of nerve fibres in the osseous spiral lamina and in the spiral ganglion to run its course

CORRELATION BETWEEN PURE TONE AUDIOGRAM AND COCHLEAR PATHOLOGY IN GUINEA PIGS INTOXICATED WITH OTOTOXIC ANTIBIOTICS

J Ylikoski

According to current knowledge, sound energy is converted into action potentials in the auditory nerve in the organ of Corti This process of transduction is generally considered to be carried out by the hair cells. In spite of the accumulation of more and more experimental and clinical data regarding the structural arrangement and the physiology of the organ of Corti there still exists a gap in the knowledge concerning the role of different types of hair cells in the transduction mechanism

Another generally accepted concept is that the cochlea functions not only as a transducer but also as a frequency and temporal analyzer According to the place principle points of maximal stimulation for each frequency are spatially arranged along the basilar membrane so that the area of optimal excitation for high frequencies is situated near the round window for the low frequencies the corresponding site is near the helicotrema. If we accept that the place principle is functioning, at least at higher frequencies, and that the hair cells are responsible for the auditory transduction then it would seem possible to study the specific role of different kinds of hair cells as well as the frequency localisation along the basilar membrane of the cochlea. This can be done by causing damage to a selected part of the cochlear partition and assessing the residual functional capacity of the cochlea by audiometric methods combined with microscopic examination of the organ of Corti.

A useful way of producing desired and selective damage inside the cochlea without causing mechanical injury or an intermixing of the cochlear fluids is to administer ototoxic antibiotics whose effect can be quantified in terms of dosage and length of treatment. The ototoxic potentials of the, useful but unruly family of basic streptomyces antibiotics" (Hawkins, 1959) was realized soon after their introduction and some of them were shown to possess a special cochleotoxic property

Although there is abundant data regarding the damage pattern in the cochlea after treatment with aminoglycoside antibiotics correlated to suprathreshold hearing measurements (pinnareflex in guinea-pigs, cochlear microphonics) there are still very few direct correlative studies between audiometric hearing threshold measurements and cochlear pathology The only studies of this kind published so far were carried out by McGee and Olzewski (1962) in four trained cats which had been treated with streptomycin and dihydrostreptomycin by McGee et al (1969) who studied one trained cat treated with gentamicin by Stebbins et al. (1969) who administered kanamycin and neomycin to five conditioned monkeys, and by Ylikoski et al. (1973) who examined conditioned guinea-pigs after the administration of gentamicin. One reason is surely the fact that the animals which are relatively easy to train for behavioural hearing determinations are usually not as suitable for cochlear microdissection and histological examination However Anderson and Wedenberg introduced in 1965 a relatively simple method for pure tone hearing testing in guinea-pigs, animals which are perhaps the best adapted for studies of cochlear pathology

Using the method of Anderson and Wedenberg for hearing measurements and the surface preparation technique (Retzius, 1884 Held 1902 Neubert 1950 Engström et al. 1964) for microscopic examination of the organ of Corti, we have

compared audiological results and cochlear pathology in guinea-pigs treated with various doses of gentamicin, kanamycin or neomycin for various lengths of time in an attempt to answer the following questions

1) What is the relation between the degree of hair cell injury and auditory sensitivity?
2) Is it possible to make a systematic investigation of frequency localisation in the cochlea by allowing hearing loss to reach the desired cut-off frequency stopping the treatment at that point and correlating the extent of achieved hair cell loss with the final audiogram?

MATERIAL AND METHODS

Forty-two healthy young guinea-pigs, weighing at the beginning of the experiment 250–350 g, were used in the experiment. The animals were conditioned to respond to pure tone stimuli by the technique described elsewhere (Ylikoski et al., 1973) and the hearing threshold for frequencies *0.5 kHz, 1 kHz, 1.5 kHz, 2 kHz*, 3 kHz 4 kHz, 8 kHz and 12 kHz was determined in each animal by the method introduced by Anderson and Wedenberg (1965). Most of the animals were monauralized by the surgical destruction of the left cochlea and retested after recovery

Then each animal was given gentamicin sulphate kanamycin sulphate or neomycin sulphate subcutaneously twice daily for various lengths of time. The dosage schedule is presented in Tables 1–3 All animals but one (K 4) were allowed to survive at least 10 days after the last injection and their hearing was tested until a stable threshold curve was obtained on three separate occasions. The survival time for each animal is shown in Tables 1–3

After the final audiogram the animals were anesthesized with chloroform, decapitated and the temporal bones were removed. The bulla was opened the stapes extracted, the round window membrane was opened and a small opening was made in the apex. The cochleas were perfused with 1 % or 2 % veronal-buffered osmium tetroxide and immersed in the fixation fluid for 1 hour 30 minutes. The specimens were then dehydrated in alcohol and embedded in Epon. Embedded cochleas were divided along the mid-modiolus with a 0.1 mm thick circular saw. Each half coil was cut into a block with a flat surface which included the whole cochlear duct. Each block containing a half coil was thinned and mounted on a glass slide basal membrane downwards (Ernstsson, 1971 1972). The specimens were studied through a water lens 40x with a Zeiss photomicroscope equipped with the interference contrast system (Nomarski 1955) The hair cells were counted and each cell marked as

CASE	DRUG	DOSE	DURATION OF TREATMENT	SURVIVAL TIME
G10	GENTAMICIN	150mg/kg/day	3 days	13 days
G11			4	16
G12			6	18

According to current knowledge, sound energy is converted into action potentials in the auditory nerve in the organ of Corti This process of transduction is generally considered to be carried out by the hair cells. In spite of the accumulation of more and more experimental and clinical data regarding the structural arrangement and the physiology of the organ of Corti there still exists a gap in the knowledge concerning the role of different types of hair cells in the transduction mechanism

Another generally accepted concept is that the cochlea functions not only as a transducer but also as a frequency and temporal analyzer According to the place principle points of maximal stimulation for each frequency are spatially arranged along the basilar membrane so that the area of optimal excitation for high frequencies is situated near the round window for the low frequencies the corresponding site is near the helicotrema If we accept that the place principle is functioning at least at higher frequencies, and that the hair cells are responsible for the auditory transduction then it would seem possible to study the specific role of different kinds of hair cells as well as the frequency localisation along the basilar membrane of the cochlea. This can be done by causing damage to a selected part of the cochlear partition and assessing the residual functional capacity of the cochlea by audiometric methods combined with microscopic examination of the organ of Corti.

A useful way of producing desired and selective damage inside the cochlea without causing mechanical injury or an intermixing of the cochlear fluids, is to administer ototoxic antibiotics whose effect can be quantified in terms of dosage and length of treatment. The ototoxic potentials of the useful but unruly family of basic streptomyces antibiotics" (Hawkins, 1959) was realized soon after their introduction and some of them were shown to possess a special cochleotoxic property

Although there is abundant data regarding the damage pattern in the cochlea after treatment with aminoglycoside antibiotics correlated to suprathreshold hearing measurements (pinnareflex in guinea-pigs, cochlear microphonics) there are still very few direct correlative studies between audiometric hearing threshold measurements and cochlear pathology The only studies of this kind published so far were carried out by McGee and Olzewski (1962) in four trained cats which had been treated with streptomycin and dihydrostreptomycin by McGee et al (1969) who studied one trained cat treated with gentamicin by Stebbins et al. (1969) who administered kanamycin and neomycin to five conditioned monkeys, and by Ylikoski et al. (1973) who examined conditioned guinea-pigs after the administration of gentamicin One reason is surely the fact that the animals which are relatively easy to train for behavioural hearing determinations are usually not as suitable for cochlear microdissection and histological examination. However Anderson and Wedenberg introduced in 1965 a relatively simple method for pure tone hearing testing in guinea-pigs, animals which are perhaps the best adapted for studies of cochlear pathology

Using the method of Anderson and Wedenberg for hearing measurements and the surface preparation technique (Retzius, 1884 Held 1902 Neubert 1950 Engström et al 1964) for microscopic examination of the organ of Corti, we have

compared audiological results and cochlear pathology in guinea-pigs treated with various doses of gentamicin, kanamycin or neomycin for various lengths of time in an attempt to answer the following questions

1) What is the relation between the degree of hair cell injury and auditory sensitivity?
2) Is it possible to make a systematic investigation of frequency localisation in the cochlea by allowing hearing loss to reach the desired cut-off frequency stopping the treatment at that point, and correlating the extent of achieved hair cell loss with the final audiogram?

MATERIAL AND METHODS

Forty-two healthy young guinea-pigs weighing at the beginning of the experiment 250–350 g, were used in the experiment. The animals were conditioned to respond to pure tone stimuli by the technique described elsewhere (Ylikoski et al., 1973) and the hearing threshold for frequencies 0.5 kHz, 1 kHz, 1.5 kHz, 2 kHz, 3 kHz, 4 kHz, 8 kHz and 12 kHz was determined in each animal by the method introduced by Anderson and Wedenberg (1965). Most of the animals were monauralized by the surgical destruction of the left cochlea and retested after recovery

Then each animal was given gentamicin sulphate, kanamycin sulphate or neomycin sulphate subcutaneously twice daily for various lengths of time. The dosage schedule is presented in Tables 1–3. All animals but one (K 4) were allowed to survive at least 10 days after the last injection and their hearing was tested until a stable threshold curve was obtained on three separate occasions. The survival time for each animal is shown in Tables 1–3

After the final audiogram the animals were anesthesized with chloroform decapitated, and the temporal bones were removed. The bulla was opened, the stapes extracted, the round window membrane was opened, and a small opening was made in the apex. The cochleas were perfused with 1 % or 2 % veronal-buffered osmium tetroxide and immersed in the fixation fluid for 1 hour 30 minutes. The specimens were then dehydrated in alcohol and embedded in Epon. Embedded cochleas were divided along the mid-modiolus with a 0.1 mm thick circular saw. Each half coil was cut into a block with a flat surface which included the whole cochlear duct. Each block containing a half coil was thinned and mounted on a glass slide basal membrane downwards (Ernstsson, 1971, 1972). The specimens were studied through a water lens 40x with a Zeiss photomicroscope equipped with the interference contrast system (Nomarski 1955). The hair cells were counted and each cell marked as

"present" or "missing" in accordance with Engström et al. (1966) Ernstson (1971 1972) Ylikoski et al. (1973) in a cytocochleogram. From this cochleogram the percentage of missing outer hair cells (OHCs) and inner hair cells (IHCs) per millimetre of cochlear length was calculated and plotted on a graph. Selected pieces from the mounted block were reoriented and remounted in Epon. The remounted specimens were used for 0.5–1 micron sections for light microscopy and for thin sections for electron microscopy

For a graphic presentation of the data both histological and audiological results were plotted on the same graph. The changes in hearing, in decibels, and the percentage of damaged hair cells in each millimetre segment were represented along the ordinate axis, the length in millimetre of the basilar membrane measured from the round window and the frequencies, on a logarithmic scale, were represented along the abscissa axis. The specific distance representative of each frequency in the graph was chosen on the basis of earlier studies (Békésy 1947 1960 Schuknecht 1953 Stebbins et al. 1969) and on our preliminary results (Ylikoski et al. 1973) which were as follows 12 kHz at 3 5 mm, 8 kHz at 5 0 mm, 4 kHz at 8 mm, 3 kHz at 9.5 mm, 2 kHz at 11 0 mm, 1 5 kHz at 12.5 mm, 1 kHz at 14 mm and 0.5 kHz at 17 mm.

RESULTS

Because the main aim of the present work was to induce hearing losses of various degrees which could be related to corresponding changes in morphology the results are presented according to the changes in hearing sensitivity The following groups were identified

1) *No change or slight elevation in hearing threshold*

This group included animals which revealed unaltered hearing sensitivity compared with pretreatment audiograms, or no more than a 10 dB deterioration at frequencies ranging from 0.5 kHz to 8 kHz, or no more than a 20 dB impairment at the highest frequency tested (12 kHz) In some cases elevations of the hearing threshold were observed during treatment, especially at the highest frequencies, but these returned to the pretreatment level soon after the administration of drugs was discontinued.

This group consisted of ten animals (G 10, 11 12, 13 14 15 16, 17 18 and K 10) Of these 5 animals were treated with a low dose of gentamicin for a long period (29 days) (G 14 15 16, 17 and 18) 4 animals (G 10 11 12 and 13) were treated with a high dose (150 mg) of gentamicin for a short period (5–6 days) and one animal (K 10) was given kanamycin 400 mg for 6 days (Table 1)

All animals except one (G 17) displayed preserved pinnareflex at the pretreatment level at the time of decapitation.

In spite of unchanged pure tone audiograms, all the animals displayed notable but, in most cases, slight hair cell damage which commonly was evenly distributed as a scattered loss of the OHCs over the entire cochlea. However in three cases there was a relatively severe loss of OHCs particularly in the basal coil (G 17 18 and K 10) (Fig. 1) G 18 showed an extensive

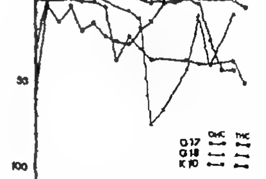

Fig. 1. The extent of hair cell damage in three selected that displayed unchanged pure tone audiograms after treatment with gentamicin 50 mg/kg for 29 days (G 17 and G 18) or kanamycin 400 mg/kg for 6 days (K 10).

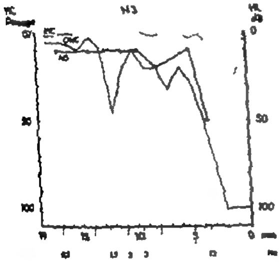

Fig. 2. The results of histological and audiological examinations on the three animals in group A whose hearing losses were the most abrupt. The changes in hearing in decibels, and the percentage of damaged hair cells in each mm segment are represented along the ordinate axis, the length in mm of the basilar membrane and the corresponding frequency are represented along the abscissa axis.

a) K 13 was given kanamycin 400 mg/kg for 6 days
b) N 3 was given neomycin 250 mg/kg for 7 days
) K 21 was given kanamycin 200 mg/kg for 16 days.

of the hearing threshold at 8 kHz and a 35 dB elevation at 12 kHz (Fig. 2c). Histopathological data disclosed a nearly total loss of OHCs in the extreme basal 5 mm area after which the OHCs remained in gradually increasing numbers so that at 9 mm only 45 % were missing. This damage of about 45 % extended up to 17 mm where there was some improvement. The IHCs were generally well preserved except at a point 2 mm from the round window where there was a loss of 50 %.

B) The second group of *three animals* (G 21 24 and K 12) was observed to *have quite similar hearing impairment* and histopathological changes. This is why they are presented as one group (*Fig. 3*). The hearing was normal or nearly normal at lower frequencies up to 2 kHz. At 3 kHz it clearly deteriorated (about 30 dB) and at higher frequencies deterioration increased further (about 40 dB). A histopathological examination revealed an almost total loss of OHCs in the basal 9 mm region

OHC loss of up to 70 % in a narrow region 7 mm to 9 mm from the basal end The IHCs were intact in the cochlea of every animal except one (K 10) which revealed a degeneration in the apex of about 30 %

II) Abrupt hearing loss

Relatively abrupt hearing loss was consid ered to be induced when the threshold shift was at least 30 dB over a frequency range of one and one-half octaves. This exper imental group consisted of 19 animals which were given various antibiotics for different periods of time and in varying dosages as follows 3 animals were treated with neomycin (250 mg/kg) for seven days (N 3 N 4 N 13) 8 animals were given gentamicin (100 mg/kg) for between 10 and 21 days (G 21 22 24 26 28 33 35 and GA 14), one animal was given gentamicin (50 mg/kg) for 29 days (G 19) 3 animals were treated with kanamycin (400 mg/kg) for 6–7 days (K 9 12 and 13) and 5 animals were given kanamycin (200 mg/kg for 16 days (K 19 21 22 23 and 24) (Table 2)

The hearing loss was generally observed initially as a high tone loss with the elevation slowly shifting towards the lower frequencies until all frequencies above 2 kHz were involved This was the borderline because there were no cases where the abrupt threshold shift or "cut-off frequency" was observed at a lower level than 2 kHz (Those animals in which the hearing was observed to continue to deteriorate weeks after the cessation of treatment until deafness with a flat curve resulted were not included in this group)

Some of these animals can be grouped into sub-groups on the basis of the similarity of hearing changes and associated hair cell pathology

A) The first group comprises three animals (K 13 K 21 and N 3) of which two had abrupt high tone losses and relatively sharply demarcated hair cell injuries located below the 7 mm level. K 21 was placed in this group because it showed a sharp transition from total OHC degeneration to 50 % damage within the same level of the cochlea, although the OHCs of the first row were missing as high up as the apex.

1) K 13 exhibited an audiogram with unchanged hearing at 4 kHz (Fig. 2a) At 8 kHz there was a drop of 60 dB and at 12 kHz the hearing was further impaired by 20 dB for a total drop of 80 dB compared with the pretreatment audiogram An histological examination disclosed that the OHCs were totally missing in the basal 4 4 mm along the basilar membrane and the IHCs were almost totally absent in the basal 3 mm area with a sharp transition to a nearly normal hair cell pattern within 2.5 mm of the cochlear length.
2) N 3 displayed a 10 dB loss at lower frequencies up to a frequency of 8 kHz with an abrupt shift of 40 dB for a total of 50 dB at 12 kHz (Fig 2b) Correspondingly all the OHCs were missing in the lowermost 3 mm along the basilar membrane but more than 50 % were present at the 4 mm point and about 80 % remained at 6 mm beyond which there was a loss of about 30 % until the 14 mm level where the cellular pattern was almost intact There was a 25 % loss of IHCs at the 2 mm point in other areas the IHC-pattern was nearly normal.

   Both of these animals which experienced a relatively abrupt high tone loss and a sharp transition from total sensory cell loss to an almost normal pattern were given large doses of antibiotics for a short time – for the former (K 13) 400 mg/kg kanamycin for 6 days for the latter (N 3) 250 mg/kg neomycin for 7 days. The changes, however resemble those observed by Stebbins et al (1969) when they used very small doses on monkeys for a long period of time (several hundred days)
3) K 21 displayed a 30 dB loss at lower frequencies in the range 0 5 kHz to 2 kHz whereafter there was a 20 dB shift at 4 kHz and a further 20 dB elevation

tern was observed at the 15 mm point. In G 28 and G 35 the IHCs had suffered damage only in the hook region. In G 26 there was a total loss of IHCs up to the 7 mm level and the whole organ of Corti had disappeared in many places in the same area.

D) The following three animals K 22, K 24 and K 19 were given 200 mg/kg kanamycin for 16 days and this treatment induced an almost equal hearing impairment in each of them (Fig. 5). There was an average 20–30 dB loss in the lower frequency range up to 2 kHz, then a rather steeply sloping shift so that the elevation of the hearing threshold was about 50 dB at the frequency of 3–4 kHz, 70 dB at 8 kHz and 80 dB at 12 kHz. The histopathological data disclosed extensive sensory cell damage in each cochlea. The OHCs were virtually missing basally on the average up to the 8 mm point beyond which more and more OHCs remained, but there was a pronounced loss, about 20–30 %, extending to the apex. The IHCs were severely injured in K 22. They as well as the whole organ of Corti were absent in the lowermost 5 mm along the basilar membrane. After this point there was a 50 % degeneration of IHCs up to 8 mm from the round window. K 24 experienced only a 50 % injury to the IHCs in the extreme basal end up to 3.5 mm. K 19 exhibited the slightest IHC-damage of this group and then only in the hook area where it did not exceed 30 %.

E) N 4 demonstrated a relatively slight elevation of the hearing threshold, 40 dB at the frequency of 12 kHz and 20 dB at frequencies from 8 kHz to 3 kHz and 10 dB at lower frequencies (Fig. 6). This was related to histological changes which revealed an almost total OHC loss in the basal 6 mm region followed by about 50 % damage up to the 11 mm level beyond which only the first row of OHCs were missing up to 17 mm along the cochlea. The IHCs were generally well preserved. About 25 % were absent in the hook region, then intact to the 17 mm point where in spite of the well preserved OHCs, almost all IHCs were missing to the apex.

F) The following two animals, N 13 and G 33, were found to have almost similar hearing losses (Fig. 7). N 13 had received neomycin 250 mg/kg for as many days as N 4 but disclosed very

Fig. 6

along the cochlea after which the damage gradually lessened to a nearly normal OHC-pattern within 3–4 mm In K 12 however the first row of OHCs was missing to the apex

In G 24 and K 12 there was a complete loss of IHCs in the extreme basal 3 mm region. This loss was associated with a degeneration of the whole organ of Corti G 21 exhibited about 50 % damage to the IHCs at the corresponding level with the IHCs reaching nearly normal preservation within 2–4 mm in the apical direction from this 3 mm point

C) The animals G 26 G 28 and G 35 were grouped together because they also showed rather similar hearing losses. The average audiogram of this group revealed a slight elevation of the hearing threshold at 0.5 kHz and 1 kHz (10–20 dB) which further deteriorated at higher frequencies, the loss being 30 dB at 2 kHz and 65 dB at 4 kHz (Fig. 4) At 8–12 kHz it was somewhat better 50–60 dB In the histopathological examination extensive damage was observed to the OHCs which were totally missing in the basal coil of each cochlea the average nearly total loss of the OHCs extending up to the 10 mm point along the basilar membrane An almost normal OHC pat

Fig. 9. Extent of audiological and sensory cell damage in G 19 given gentamicin 50 mg/kg for 29 days, and in K 9 given kanamycin 400 mg/kg for 6 days. The audiogram of G 19 dips at 4 kHz, that of K 9 dips at 3 kHz.

Fig. 10. Results of audiological and histological examinations in GA 14 given gentamicin 100 mg/kg for 11 days, and K 23, given kanamycin 200 mg/kg for 16 days. Both animals displayed a "dip" in their audiograms at 4 kHz.

poor hearing after treatment It had deteriorated 40–45 dB at lower frequencies from 0.5 kHz to 2 kHz and the hearing sensitivity dropped steeply at higher frequencies to the 70 dB level at 3–4 kHz and to the 90 dB level at 8–12 kHz Correspondingly all the hair cells as well as the organ of Corti had practically disappeared in the basal 6 mm area along the basilar membrane after which there was an approximate 25 % injury to the IHCs until 13 mm Almost all the OHCs were missing up to 14 mm region of the cochlea.

Although G 33 showed a similar hearing capacity as N 13 the histopathological data of the cochlea was more related to the previously presented cases of gentamicin injury in groups B and C with the difference that in G 33 the IHCs were largely missing in the uppermost 2 mm area of the cochlea. G 33 was the only animal treated with gentamicin in which this apical IHC degeneration was revealed

G) G 22 displayed a flat hearing loss of 10 dB at lower frequencies up to 2 kHz whereafter there was a drop of 40 dB at both 4 kHz and at higher frequencies tested (Fig. 8) Microscopic examin-

ation demonstrated remarkably less damage to the hair cells than in other animals with corresponding hearing impairments. The IHCs were almost intact in the entire cochlea and the OHCs had suffered only about 50 % damage in the lowermost 6 mm along the length of the cochlea.

II) G 19 K 9 GA 14 and K 23 formed a group which had in common a dip in the hearing threshold at 3–4 kHz and which had somewhat better hearing at higher frequencies. The abruptness of hearing changes in this group did not fill the demands mentioned above

1) G 19 showed a slight hearing impairment with a 10 dB loss at 2 kHz and lower frequencies and a 20 dB dip at 4 kHz followed by a 30 dB improvement at 8 kHz (Fig. 9)

   The organ of Corti of this animal had suffered the following damage all the OHCs were absent from the basal end to 1.5 mm about 30 % were missing at the 4 mm point from the round window after which about 20 % were missing up to the 9 mm point. The IHCs were intact in the whole cochlea.

2) K 9 had a greater hearing impairment with a general 10–20 dB hearing loss which increased by 20 dB at 2 kHz. Its hearing was 10 dB better at 4 kHz and 8 kHz with, however a 30 dB dip at 1[illegible] kHz. Cochlear histopathology revealed a [illegible]0 % injury to IHCs in the round window area. The OHCs were completely missing in the lowermost 1.5 mm from where there was an average of 50 % damage until the 17 mm level. There was a "notch" with about 85 % damage between 7 mm and 9 mm possibly corresponding to the functional dip in the audiogram

3) K 23 had a general 20 dB hearing deterioration at all frequencies plus a [illegible]0 dB dip at 4 kHz (Fig. 10) Microscopic examination disclosed relatively severe damage About 60 % of the IHCs were missing in the hook area, but elsewhere they were almost intact. The OHCs totally disappeared in the basal 2.5 mm region of the cochlear duct, and about 50 % were missing up to the 11 mm point after which the first row of OHCs was defective up to 16 mm.

4) The audiogram of GA 14 showed an evenly descending curve from a frequency of 0.5 kHz to 4 kHz where the hearing loss was 55 dB At two higher frequencies there was some hearing improvement with only a 30 dB loss. Cochlear histopathology demonstrated a maximum of 20 % damage in the IHC-pattern but the OHCs were totally destroyed up to the 11 mm level and partially damaged to the 16 mm point.

III) *Hearing loss with a flat curve*

A) This group consisted of five animals (N 5 6, 7 10 and K 11) which all demonstrated similar hearing losses with about a 30–60 dB drop at each frequency (Fig. 11) The histological examination of the cochlea showed severe damage to the OHCs which were often present only in the most apical part of the cochlea. The IHCs were sometimes also severely degenerated in some areas along the cochlear duct. There were large *variations* in the extent of histological damage

B) This group contained seven animals, some from each antibiotic group (K 4 14 15 N 11 15 G 23 and 34). It was usually possible to distinguish them from the other animals already during treatment due to an extensive deterioration in hearing sensitivity which occurred at a very early stage. The hearing impairment continued to increase in some cases weeks after the cessation of the treatment. The common characteristic of this group was a nearly flat audiogram with a general 80–90 dB hearing loss at all frequencies (Fig. 12) This resembles one group of patients with ototoxic hearing loss described by Rosal et al. (1961) Cochlear *histopathology* revealed a severely damaged cochlea in all animals. Total disappearance of the sensory cells from the entire cochlea was, however *never* pro-

Fig. 11

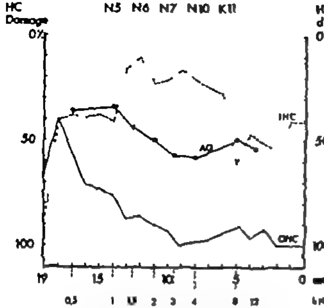

Fig. 11 Mean values of hearing-threshold elevation and hair cell damage in five animals that suffered flat hearing loss. N 5, N 6 and N 7 were given neomycin 250 mg/kg for 8 days and N 10 for 7 days, K 11 received kanamycin 400 mg/kg for 6 days.

Fig. 12

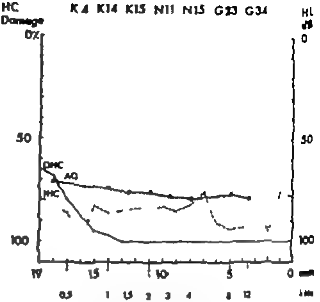

Fig. 12. Mean values of hearing-threshold elevation and hair cell damage in seven animals that suffered flat hearing loss and nearly total destruction of the organ of Corti. K 4 was given kanamycin 300 mg/kg for 12 days, K 14 and K 15 kanamycin 200 mg/kg for 20 days, N 15, neomycin 250 mg/kg for 5 days and N 11 for 7 days, and G 23 and G 24 gentamicin 100 mg/kg for 16 days.

duced there were always at least some OHCs left in the uppermost part of the cochlea. In one animal (K 15) all the IHCs had disappeared and in two others there were only six (G 34) and four (K 14) IHCs left. In all of these profusely destroyed cochleas, the supporting structures also revealed significant damage and in many places in the basal coil the entire organ of Corti had disappeared and had been replaced by a layer of flattened epithelium. The supporting elements, especially pillar cells, were, however, usually relatively well preserved from about the 8 mm point along the basilar membrane upwards in spite of complete hair cell degeneration.

DISCUSSION

A) The anatomical frequency scale

In the abrupt hearing loss group II there were 12 animals which exhibited a relatively distinct change in hearing sensitivity at a narrow frequency range (within one octave or one and one-half octave) and they had correspondingly relatively restricted lesions along the basilar membrane with a rather sharp transition from total destruction of the OHCs to a nearly normal pattern. These changes, however, were generally much less distinct than those reported by Stebbins et al. (1969) in four monkeys. However, the data obtained seems to be reliable enough to permit some conclusions regarding the spatial arrangement of frequency localisation on the cochlear duct.

The audiogram of N 3 (Fig. 2b) showed an abrupt loss of hearing at 12 kHz. An histopathological examination of the cochlea revealed a total loss of OHCs and some of the IHCs to the 3 mm point from the basal end beyond which the sensory cells were better preserved so that at the level of 4 mm the IHCs were intact and more than 50% of the OHCs remained. From this one can conclude that the area of maximum excitability for 12 kHz lay below

the 4 mm point, and for 8 kHz above the 3 mm point. Thus the area from 3 mm to 4 mm from the basal end of this cochlea was between the regions of optimal excitability for frequencies between 8 kHz and 12 kHz.

Guinea-pig K 13 (Fig. 2a) had normal hearing at lower frequencies up to 4 kHz with an abrupt threshold shift at 8 kHz. Cochlear histopathology disclosed an almost total loss of the OHCs up to the 4.4 mm point after which a rapid transition to an intact cellular pattern took place within 2.5 mm. It was reasonable to assume that the region of maximum excitability for 8 kHz was located below the 7 mm point, and that for 4 kHz it was located from the 4.4 mm region towards the apex. Thus it follows that the area between 4.4 mm and 7 mm from the round window corresponds to the area between the points of maximal stimulation of frequencies between 4 kHz and 8 kHz.

The audiological examination of K 21 (Fig. 2c) revealed an abrupt 40 dB threshold shift between the frequencies of 3 kHz and 8 kHz. The histological examination of the cochlea showed a nearly complete loss of the OHCs up to the 5 mm level beyond which there was a transition towards a better preserved area so that at the 9 mm point only 45% of the OHCs were degenerated. This should account for the hearing loss of less than 50 dB (Schuknecht 1953 Bredberg, 1968). This in turn would mean that the area of maximal stimulation for 8 kHz was situated below the 9 mm point and for 3 kHz upwards from the 5 mm point towards apex. It can, therefore be concluded that the region between 5 mm and 9 mm along the basilar membrane was connected to the areas of maximal stimulation for frequencies between 3 kHz and 8 kHz.

The average audiogram of group II/B (Fig. 3) showed a 40 dB shift in hearing sensitivity between the frequencies of 2 kHz and 4 kHz. The histological examinations revealed that the OHCs were almost entirely missing up to the 9 mm level beyond which there was a transition towards the normal cellular pattern so that at the 12 mm level only 25% of the OHCs were absent. From this it was clear that the area of maximal excitation for 2 kHz was above the 9 mm point, and for 4 kHz below

AREA BETWEEN mm	CASE	FREQUENCIES
3 – 4	[illegible]	12–8 kHz
4.4 – 7.0	K13	8–4 kHz
5 – 9	K21	8–3 kHz
9 – 12	II B	4–2 kHz
9 – 14	II C	4–2 kHz
8 – 12	II D	4–2 kHz

Table 4 *The data obtained from 12 animals with abrupt hearing loss on which the frequency analysis (Fig 13) is based. On the left are given the segments of the basilar membrane we examined and which are thought to be related to the range of frequencies given on the right. Groups II B C and D represent the mean values of three guinea-pigs with similar audiological and histological impairment. Group II B includes guinea-pigs G 21 G 24 and K 12 group II C. G 26 G 28 and G 35 group II D K 19 K 22 and K 24*

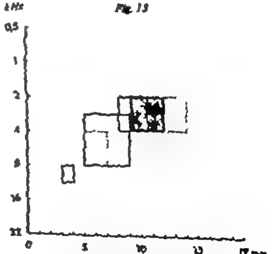

Fig. 13. Frequency analysis based on data in Table 4 plotted so that the frequencies are presented along the abscissa axis and the length, in millimetres, of the basilar membrane measured from the round window are presented along the ordinate axis. The six rectangles represent the animals studied.

the 12 mm point Thus the area between 9 mm and 12 mm from the base of this cochlea should correspond to the area between the points of optimal stimulation for frequencies between 2 kHz and 4 kHz

Similar audiological changes were obtained in groups II/C (Fig. 4) and II/D (Fig. 5) and these were related to the absence of the OHCs up to the 9 mm region for the former and up to the 8 mm region for the latter The upper margin of the transitional region for the two groups were respectively the 14 mm point and the 12 mm point.

The data for the above analysis is shown in Table 4 and in figure 13 in which the distance along the basilar membrane is plotted as a function of frequency Frequency is represented along the ordinate on a logarithmic scale with the assumption that the upper limit of frequency sensitivity for the guinea pig cochlea lies at about 32 kHz.

B) Correlation between hair cell damage and hearing sensitivity

Although there is some difference of opinion regarding the roles of various types of hair cells in the cochlear function (Ward & Duvall 1971 Lynn & Sayers 1970 Billone & Raynor 1973) there is considerable data indicating that the OHCs alone are responsible for the transduction of auditory stimuli near the threshold and the IHCs for higher intensities (Lurie 1937 Schuknecht 1953 Bredberg 1968 Dallos et al 1972) If we also take into account the orderly arrangement of frequency responses along the cochlear duct based on the large amount of physical, physiological and morphological evidence both in humans and in experimental animals (Growe et al. 1934 Stevens et al. 1935 Davis et al. 1949 Bekesy 1947 1960 Schuknecht 1953b Johnstone et al. 1970 Stebbins et al 1969) several interesting observations can be made from the above results.

Group I

The pure tone threshold was nearly unchanged for these animals although there was often noticeable, sometimes even pronounced lesion of the OHCs. From this it can be concluded that the pure tone audiogram does not reflect the low or moderate level pathology of the cochlear sensory cells, and that even a complete loss of the OHCs in a relatively narrow region can occur without a corresponding change in the auditory function measured in this way (Ylikoski et al. 1973) Similar results obtained by other methods are reported by *Bredberg (1968) and Ward & Duvall (1971)* and by Eldredge & Miller (1969)

Groups II and III

All animals included in these groups displayed impaired hearing which in some animals was relatively abrupt and therefore it was possible to correlate hearing impairment with a rather restricted change in the cytocochleogram and thus to use the correlation in the investigation of frequency distribution along the cochlear duct. For correlation studies between hair cell injury and hearing loss all the animals of these two groups were used

On the basis of the previously given frequency map the percentage of sensory cell degeneration at each millimetre point was related to a corresponding hearing loss in decibels. The results of this correlation are illustrated in the accompanying Table 5 where the animals are grouped according to the degrees of hair cell damage as follows

I) All the sensory cells degenerated. This group included all the cases where at least 80% of both the IHCs and the OHCs were missing in the corresponding cochlear region Supporting structures were variably affected with the complete disappearance of the organ of Corti in some areas to those with well preserved pillar cells in others. The average hearing loss resulting from this nearly total loss of sensory cells was 79 dB and there were no significant differences between the hearing results at higher or lower frequencies.

How valid our hearing test method in measuring such high intensity tones is

HC	DAMAGE	12	8	4	3	2	1.5	1	0.5	MEAN HEARING LOSS dB

Table 5 *Relationship between various degrees of hair cell damage and subsequent hearing losses at various frequencies.*

is not clear. Whether the animals are really responding to the sound waves or to the air vibrations produced by these high-intensity tones, is a question that cannot be answered here. However responses to air vibrations seem rather likely especially in the group of animals which had almost total hair cell destruction in the entire cochlea (group III/B) (Schuknecht, 1953b).

2) All the OHCs degenerated (75–100%) and a portion of the IHCs (11% to 79%) degenerated. In these cases there were probably no functioning OHCs and the damage to the IHCs varied greatly. The average hearing loss for this group was 55 dB which shows that even a relatively few preserved IHCs (21%) appear to improve hearing capacity remarkably. On the other hand a relatively well preserved IHC-pattern (89% left) cannot account for better hearing if all the OHCs are degenerated.

3) All the OHCs degenerated (75–100%), less than 11% of the IHCs degenerated. This group showed an average hearing loss of 42 dB. This therefore, indicates the degree of hearing impairment when all the OHCs are missing but the IHCs are almost intact.

4) OHC-degeneration from 40% to 74%, IHC-degeneration less than 11%. The average hearing loss was 38 dB which corresponds to the condition when the first and second row of the OHCs are degenerated but the third is preserved.

5) OHC-degeneration from 20% to 39%. The average hearing loss was 18 dB which corresponds to the condition when only the first row of the OHCs is missing.

The neomycin-treated animals that exhibited total IHC-degeneration (Figs. 6 and 11) with about 50% damage to the OHCs (in one case, N 4, there was an OHC degeneration of about 25%) had a hearing deterioration that was apparently related to the OHC damage. The apical IHC loss does not usually seem to have any influence on auditory sensitivity although opposite results have been reported elsewhere (Stebbins et al. 1973).

In earlier papers, where a correlation has been made between auditory impairment and sensory cell damage, it has been cus-

the 12 mm point Thus the area between 9 mm and 12 mm from the base of this cochlea should correspond to the area between the points of optimal stimulation for frequencies between 2 kHz and 4 kHz

The apical IHC loss does not usually seem to have any influence on auditory sensitivity although opposite results have been reported elsewhere (Stebbins et al. 1973)

In earlier papers, where a correlation has been made between auditory impairment and sensory cell damage, it has been cus-

the 12 mm point. Thus the area between 9 mm and 12 mm from the base of this cochlea should correspond to the area between the points of optimal stimulation for frequencies between 2 kHz and 4 kHz.

Similar audiological changes were obtained in groups II/C (Fig. 4) and II/D (Fig. 5) and these were related to the absence of the OHCs up to the 9 mm region for the former and up to the 8 mm region for the latter The upper margin of the transitional region for the two groups were respectively the 14 mm point and the 12 mm point.

The data for the above analysis is shown in Table 4 and in figure 13 in which the distance along the basilar membrane is plotted as a function of frequency Frequency is represented along the ordinate on a logarithmic scale with the assumption that the upper limit of frequency sensitivity for the guinea-pig cochlea lies at about 32 kHz

B) Correlation between hair cell damage and hearing sensitivity

Although there is some difference of opinion regarding the roles of various types of hair cells in the cochlear function (Ward & Duvall 1971 Lynn & Sayers, 1970 Billone & Raynor 1973) there is considerable data indicating that the OHCs alone are responsible for the transduction of auditory stimuli near the threshold and the IHCs for higher intensities (Lurie 1937 Schuknecht 1953 Bredberg, 1968 Dallos et al 1972) If we also take into account the orderly arrangement of frequency responses along the cochlear duct based on the large amount of physical, physiological and morphological evidence both in humans and in experimental animals (Growe et al. 1934 Stevens et al. 1935 Davis et al., 1949 Bekesy 1947 1960 Schuknecht 1953b Johnstone et al 1970 Stebbins et al., 1969) several interesting observations can be made from the above results.

Group I

The pure tone threshold was nearly unchanged for these animals although there was often noticeable sometimes even pronounced lesion of the OHCs. From this it can be concluded that the pure tone audiogram does not reflect the low or moderate level pathology of the cochlear sensory cells, and that even a complete loss of the OHCs in a relatively narrow region can occur without a corresponding change in the auditory function measured in this way (Ylikoski et al. 1973) Similar results obtained by other methods are reported by Bredberg (1968) and Ward & Duvall (1971) and by Eldredge & Miller (1969)

Groups II and III

All animals included in these groups displayed impaired hearing which in some animals was relatively abrupt and therefore it was possible to correlate hearing impairment with a rather restricted change in the cytocochleogram and thus to use the correlation in the investigation of frequency distribution along the cochlear duct. For correlation studies between hair cell injury and hearing loss, all the animals of these two groups were used

On the basis of the previously given frequency map the percentage of sensory cell degeneration at each millimetre point was related to a corresponding hearing loss in decibels. The results of this correlation are illustrated in the accompanying Table 5 where the animals are grouped according to the degrees of hair cell damage as follows

1) All the sensory cells degenerated. This group included all the cases where at least 80% of both the IHCs and the OHCs were missing in the corresponding cochlear region. Supporting structures were variably affected with the complete disappearance of the organ of Corti in some areas to those with well preserved pillar cells in others. The average hearing loss resulting from this nearly total loss of sensory cells was 79 dB and there were no significant differences between the hearing results at higher or lower frequencies.

   How valid our hearing test method in measuring such high intensity tones is

Statistical comparison

Hearing loss seemed to be a function of hair cell loss involving both OHCs and IHCs. When data for all the animals which had suffered hearing loss (group II and III) were pooled, a statistically significant relationship between hearing loss and hair cell loss was evident. The correlation coefficient was computed for the percentage loss of both OHCs and IHCs per millimetre of each segment of the basilar membrane thought to be representative of each frequency and the hearing threshold at each frequency tested. The correlation coefficient between the percentage loss of OHCs and the corresponding hearing level was 0.735 which is statistically significant ($p < 0.001$)

GENERAL SUMMARY

To study and compare the degenerative changes in the cochlear hair cells of the guinea-pig after administration of gentamicin, kanamycin and neomycin, 94 guinea-pigs were treated with various doses of one of these antibiotics for various lengths of time. After survival times of from 8 days to 10 months the animals were decapitated and the pathological changes in the temporal bone were studied by light and electron microscopy. Complete cochleograms were constructed for the 68 guinea-pigs that survived to decapitation.

Selected cochlear segments in which some hair cell damage was apparent were chosen for a detailed study of both sensory cell and neural damage and for an evaluation of the relationship between the two.

Before administration of the drugs, 42 of the 94 guinea-pigs were conditioned to pure-tone hearing tests according to the technique of Anderson and Wedenberg (1965). The animals were then monaurализed and new hearing tests were performed after their recovery from this procedure. Cochlear damage was induced by administration of the ototoxic antibiotics and when a stable post treatment hearing threshold had been obtained, the animals were decapitated for studies of pathological changes in the temporal bone.

The earliest ultrastructural signs of degeneration, regardless of the antibiotic administered, were observed in the outer hair cells of the basal coil. Disarrangement of the double membranes along the sides of these cells was evident and dark inclusion bodies appeared in their subcuticular cytoplasm. At later stages the interspaces between the flattened membranes become distended, leading to vacuolization of the sides of the cells and finally with the rupture of the plasma membrane and expulsion of the cellular organelles into the Nuel's space, to the cells' complete disintegration.

At an early stage of degeneration, swellings, presumably swollen afferent nerve endings and dendrites, were occasionally seen below the inner hair cells.

The pattern of damage induced by the three antibiotics differed. Neomycin seemed to attack the hook area and the apical coil first, whereas gentamicin and kanamycin, at first, usually destroyed the outer hair cells in the upper basal coil and in the hook simultaneously. Neomycin also displayed a clearcut affinity for attacking the inner hair cells of the apex, cells seldom damaged after administration of gentamicin or kanamycin. The extent of the lesion affecting the outer hair cells was generally rather widespread. Thus the area along the cochlea between a nearly normal population of outer hair cells and complete loss of such cells was usually broader in animals treated with kanamycin than in those treated with gentamicin.

Our results demonstrate that great variations exist among individual animals as regards the effect of ototoxic antibiotics. The degree of damage by such drugs to the organ of Corti cannot therefore be quantified in terms of dosage but must be assessed by examining the hair cell population of each animal individually. Furthermore, because of the delayed effect of basic aminoglycoside antibiotics, experimental animals must be allowed to survive at least three weeks after the cessation of treatment if correlative studies between

tomary to express this correlation as good if the hearing loss has been found to be related to a significant loss of hair cells in the frequency optimal response region in the cochlea (McGee & Olzewski, 1962 Elliot 1961 1965 Bredberg 1968 Stebbins et al. 1969 Pinheiro et al 1973 Ylikoski et al 1973)

Yet in almost all studies of this kind there have been animals which have not fullfilled this criterion. Explanations for the inconsistency between audiological and histological changes have then been sought elsewhere in the cochlea or in the higher auditory pathways. In some cases there have been hearing losses which have had no corresponding damage in the cytocochleogram (Bredberg, 1968) The explanation has been looked for at the ultrastructural level where significant changes have been found in the receptor poles of the hair cells (loss or clumping of the stereocilia, giant hairs) (Lundquist & Wersäll, 1971 Bredberg, 1972) or in the cell body interfering with the cell metabolism (Lundquist & Wersäll, 1966 1967) or yet again in some cases in the synaptic regions (Spoendlin 1972) Primary changes have also been found in the spiral ganglion (Floberg et al 1949 Kellerhals et al. 1967) and in the cochlear nuclei (Stebbins et al. 1969 McGee & Olzewski, 1962)

In our material, two animals displayed a more severe hearing loss than could have been expected from the cytocochleogram Both these cases (G 22 and G 33) revealed significant degeneration of sensory cells although not to the extent observed in other animals with corresponding hearing losses. An electron microscopic examination of the cochleas did not reveal an explanation for this deviation but other factors, such as individual variations and possible damage in the higher levels of the auditory system can easily account for the differences.

A more complicated situation arises where an animal has extensive damage in the sensory and nervous elements in a relatively wide area of the cochlea but still experiences normal or nearly normal hearing. Such reports were published both by Eldredge and Miller (1969) concerning one chinchilla which exhibited severe hair cell damage but only a 20 dB hearing loss, and by Ward and Duvall (1971) in another chinchilla which displayed normal hearing in spite of the complete loss of the OHCs in the first and in part of the second turn. In these cases, two explanations have been offered

1) The animals are hearing by means of the hair cells surviving in the areas outside the maximal response point due to the widening of the area of maximal excitation when the intensity is increased.
2) The IHCs alone are responsible for auditory sensitivity

Our results generally showed a good correlation between audiological and histological changes. Thus a severe degeneration of the OHCs in the basal half of the cochlea produced a hearing loss of 40–50 dB in frequencies above 2 kHz. When both the OHCs and IHCs were severely damaged in the basal coil the hearing loss was correspondingly more severe As mentioned above there were two animals which revealed a more pronounced hearing loss than could be interpreted from the cytocochleograms alone. On the other hand, two groups of animals exhibited better hearing than expected Some of the animals belonging to group I (G 17 G 18 and K 10) displayed a moderate loss of the OHCs in the upper basal coil but still exhibited normal hearing. This is difficult to explain but it seems likely that the pure tone audiogram is not a sensitive index for low level OHC pathology in a limited region. Another group of animals with an almost total loss of sensory elements (group III/B) still responsed to delivered tones averaging 80 dB This result can be explained either by the presence of preserved OHCs in the apical 2 mm region or by the possibility that the response was perceived not by the ears but that the animals responded to tactile vibration stimuli in their footpads, body hairs or whiskers at high stimulus intensities.

Statistical comparison

Hearing loss seemed to be a function of hair cell loss involving both OHCs and IHCs. When data for all the animals which had suffered hearing loss (group II and III) were pooled, a statistically significant relationship between hearing loss and hair cell loss was evident. The correlation coefficient was computed for the percentage loss of both OHCs and IHCs per millimetre of each segment of the basilar membrane thought to be representative of each frequency and the hearing threshold at each frequency tested. The correlation coefficient between the percentage loss of OHCs and the corresponding hearing level was 0.735 which is statistically significant ($p < 0.001$)

GENERAL SUMMARY

To study and compare the degenerative changes in the cochlear hair cells of the guinea-pig after administration of gentamicin, kanamycin and neomycin, 94 guinea-pigs were treated with various doses of one of these antibiotics for various lengths of time. After survival times of from 0 days to 10 months the animals were decapitated and the pathological changes in the temporal bone were studied by light and electron microscopy. Complete cochleograms were constructed for the 68 guinea-pigs that survived to decapitation.

Selected cochlear segments in which some hair cell damage was apparent were chosen for a detailed study of both sensory cell and neural damage and for an evaluation of the relationship between the two.

Before administration of the drugs, 42 of the 94 guinea-pigs were conditioned to pure-tone hearing tests according to the technique of Anderson and Wedenberg (1965). The animals were then monaurallized and new hearing tests were performed after their recovery from this procedure. Cochlear damage was induced by administration of the ototoxic antibiotics and when a stable post-treatment hearing threshold had been obtained the animals were decapitated for studies of pathological changes in the temporal bone.

The earliest ultrastructural signs of degeneration, regardless of the antibiotic administered were observed in the outer hair cells of the basal coil. Disarrangement of the double membranes along the sides of these cells was evident and dark inclusion bodies appeared in their subcuticular cytoplasm. At later stages the interspaces between the flattened membranes become distended, leading to vacuolization of the sides of the cells and finally with the rupture of the plasma membrane and expulsion of the cellular organelles into the Nuel's space to the cells' complete disintegration.

At an early stage of degeneration, swellings, presumably swollen afferent nerve endings and dendrites, were occasionally seen below the inner hair cells.

The pattern of damage induced by the three antibiotics differed. Neomycin seemed to attack the hook area and the apical coil first whereas gentamicin and kanamycin, at first, usually destroyed the outer hair cells in the upper basal coil and in the hook simultaneously. Neomycin also displayed a clearcut affinity for attacking the inner hair cells of the apex, cells seldom damaged after administration of gentamicin or kanamycin. The extent of the lesion affecting the outer hair cells was generally rather widespread. Thus the area along the cochlea between a nearly normal population of outer hair cells and complete loss of such cells was usually broader in animals treated with kanamycin than in those treated with gentamicin.

Our results demonstrate that great variations exist among individual animals as regards the effect of ototoxic antibiotics. The degree of damage by such drugs to the organ of Corti cannot therefore be quantified in terms of dosage but must be assessed by examining the hair cell population of each animal individually. Furthermore, because of the delayed effect of basic aminoglycoside antibiotics, experimental animals must be allowed to survive at least three weeks after the cessation of treatment if correlative studies between

function and morphological changes are to be made.

A partial or total loss of outer hair cells alone in a given segment of the cochlea, was not associated with any corresponding rarefaction or loss of neurons. When the inner hair cells had degenerated as well the *number of neurons in the spiral ganglion* and spiral osseous lamina was markedly reduced provided the survival time was long enough for degeneration to have run its course In the latter specimens 10–25% of the fibres in the spiral osseous lamina and about 30% of the cells in the spiral *ganglion survived The majority of these* preserved neurons appeared normal by electron microscopy although the relative number of unmyelinated ganglion cells had increased The radially and spirally running unmyelinated fibres inside the organ of Corti remained intact as long as the inner *hair cells and supporting cells were preserved* Both efferent and afferent tunnel-crossing fibres appeared to undergo degeneration when all the sensory cells had degenerated

The secondary degeneration of first order neurons, following damage to the organ of Corti seemed to be a delayed phenomenon its full development not apparent until at least 4 weeks after the cessation of treatment.

Applying the place theory of hearing *sensitivity thresholds at each frequency* were related to the extent of hair cell loss at specific distances along the basilar membrane In this correlation it was found that all animals which displayed a deterioration of hearing also had significant disturbance in their hair cell pattern When groups of *animals with similar hearing losses were* pooled together a still better correlation between hearing losses and sensory cell destruction was achieved than in individual animals. Thus a slight hearing *loss was related to a moderate* loss of OHCs and a more severe impairment to hearing was associated with a severe degeneration of cochlear hair cells. Hence the absence of the first row of OHCs was related to a hearing loss of 18 dB *when two inner rows* of the OHCs were missing hearing had *deteriorated by 38 dB and when all the* OHCs had degenerated but the IHCs were *still essentially intact* the accompanying hearing loss was 42 dB When in addition to a complete loss of OHCs, more than 10% of the IHCs had degenerated hearing loss was correspondingly more severe and when *nearly all the cochlear hair cells* were absent, hearing loss was about 80 dB

In some of the animals, however a moderate degeneration of the OHCs was not accompanied by a corresponding change in hearing threshold

In the cochleas of 12 animals relatively *abrupt shifts in hearing threshold* were recorded and subsequent histological examination of these cochleas revealed corresponding restricted areas of hair cell damage. In these 12 animals it was possible to analyse the spatial arrangement of frequency localisation along the basilar membrane These results correlate rather well with results from earlier studies done with other methods.

ZUSAMMENFASSUNG

Vergleichende Untersuchugen über die degenerativen Veranderungen in den cochlearen Haarzellen wurden an 94 Meerschweinchen nach Verabreichung von Gentamycin, Kanamycin und *Neomycin in verschiedener* Dosierung und Zeitdauer durchgeführt. Nach einer Überlebensdauer von 8 Tagen bis 10 Monaten wurden die Tiere dekapitiert *und die pathologischen Veränderungen im Schläfenbein* licht und elektronenmikroskopisch untersucht. Vollständige Cochleogramme wurden für die 68 Meerschweinchen angefertigt, welche zu der *Dekapitation* überlebt hatten.

Die frühesten ultrastrukturellen Degenerationszeichen wurden, unabhängig von dem verabreichten Antibiotikum, in den äusseren Haarzellen der Basalwindung beobachtet. Neben Veranderungen an den lateralen Doppelmembranen kam es zum Auftreten von dunklen Einschlusskorpern im subcuticularen Cytoplasma dieser Zellen. In spateren Stadien kam es zu einer Erweiterung der Zwischenraume zwischen den abgeflachten Membranen, mit nachfolgender Vakuolisierung der lateralen Zellabschnitte und schliesslich, unter Ruptur der Plasmamembran und Austritt der Zellorganellen in den Nuel'schen Raum zu einer völligen Desintegration der Zellen. In einem frühen Stadium der Degeneration wurden Anschwellungen, vermutlich geschwollene afferente Nervenendigungen und Dendriten, unterhalb der inneren Haarzellen beobachtet.

Das durch die drei Antibiotika hervorgerufene Schadensmuster ist unterschiedlich. Neomycin schien zuerst die Basalregion und die Spitzenwindung anzugreifen, während Gentamycin und Kanamycin gewöhnlich zuerst die inneren Haarzellen in der oberen Basalwindung und im Apexgebiet gleichzeitig zerstörte. Neomycin liess auch deutlich eine schädigende Affinität zu den inneren Haarzellen der Spitze erkennen, welche nach Verabreichung von Gentamycin und Kanamycin selten geschädigt waren. Das Ausmass der Schädigung, welche die äusseren Haarzellen betraf, war im allgemeinen ausgedehnter. Das Gebiet in der Cochlea zwischen einer nahezu normalen Population von äusseren Haarzellen und einem vollständigen Ausfall dieser Zellen war gewöhnlich breiter nach Kanamycin als nach Gentamycinbehandlung.

Unsere Ergebnisse zeigen, dass bezüglich der Wirkung von ototoxischen Antibiotika grosse Variationen bei einzelnen Tieren bestehen. Der Grad der schädigenden Wirkung solcher Substanzen auf das Cortische Organ kann deshalb nicht quantitativ in Dosiseinheiten ausgedrückt, sondern sollte durch die Untersuchung der Haarzellenpopulation eines jeden einzelnen Tieres bewertet werden. Ferner sollten wegen des Verzögerungseffektes der besagten Aminoglykosid-Antibiotika die Versuchstiere mindestens drei Wochen nach Abschluss der Behandlung überleben, um entsprechende Untersuchungen über den Zusammenhang von funktionellen und morphologischen Veränderungen durchgeführt werden.

Zur Untersuchung der Beziehung zwischen einer Schädigung von sensorischen Zellen und von Neuronen in der Cochlea wurden die neuronalen Elemente in ausgewählten Cochleasegmenten, die eine Haarzellenschädigung aufwiesen, untersucht.

Ein partieller oder totaler Verlust nur von äusseren Haarzellen in einem bestimmten Cochleasegment, war nie immer entsprechenden Rarefizierung oder Verlust von Neuronen verbunden. Wenn die inneren Haarzellen degeneriert waren, dann war auch die Zahl der Neuronen in Spiralganglion und Lamina spiralis ossea deutlich vermindert, vorausgesetzt die Überlebenszeit war lange genug, dass die Degeneration ihren Verlauf nehmen konnte. Im letzteren Fall überlebten 10–25 % der Fasern an der Lamina spiralis ossea und ungefähr 40 % der Zellen im Ganglion spirale. Die Mehrheit dieser erhaltenen Neurone erschien elektronenmikroskopisch normal, obgleich die relative Anzahl von myelinfreien Ganglienzellen erhöht war. Die radiär und spiralenförmig verlaufenden myelinfreien Fasern im Inneren des Corti-Organs verblieben intakt, solange die inneren Haarzellen und Stützzellen erhalten waren. Sowohl efferente als auch afferente Tunnelüberquerungsfasern schienen der Degeneration anheimzufallen, wenn alle sensorischen Zellen degeneriert waren.

Die sekundäre Degeneration von Neuronen erster Ordnung im Anschluss an eine Schädigung des Corti-Organs schien ein verzögerter Vorgang zu sein, dessen vollständige Entfaltung nicht vor Ablauf von mindestens 4 Wochen nach Absetzen der Behandlung manifest wurde.

Zur Untersuchung der Beziehungen zwischen cochleärer Haarzellenschädigung und Hörempfindlichkeit sowie die r systematischen Ermittlung der Frequenzlokalisation in der Cochlea wurden 42 Meerschweinchen zuerst unter die Bedingungen einer Reflexhörprüfung nach der Methode von Anderson und Wedenberg (1965) gebracht und nach einseitiger Gehörausschaltung weiteren Gehörprüfungen unterzogen. Eine cochleäre Schädigung wurde durch tägliche subcutane Injektion von Gentamycin, Kanamycin oder Neomycin in toxischen Dosen gesetzt.

Nach Abschluss der Behandlung und Erreichen einer stabilen *Hörschwelle* wurden die Tiere dekapitiert und die pathologischen Veränderungen am Schläfenbein untersucht.

Entsprechend der Ortstheorie des Hörens wurden die Empfindlichkeitsschwellen in jedem Frequenzbereich zum Ausmass des Haarzellenverlustes in bestimmten Abständen an der Basilarmembran in Beziehung gesetzt. Dabei wurde gefunden, dass alle Tiere mit einer Hörverminderung auch eine signifikante Störung ihres Haarzellenmusters aufwiesen. Daraus ergab sich bei leichter Hörverminderung ein geringer Verlust von äusseren Haarzellen, während ein schwerer Hörschaden mit einer starken Degeneration der cochleären Haarzellen verbunden war. Der Ausfall der ersten Reihe von äusseren Haarzellen bedingte einen Hörverlust von 18 dB, der Ausfall von zwei inneren Reihen von äusseren Haarzellen resultierte in einem Hörverlust von 38 dB. Die Degeneration aller äusseren Haarzellen führte bei weitgehender Intaktheit der inneren Haarzellen zu einem Hörverlust von 42 dB. Waren zusätzlich zu einem vollständigen Verlust der *äusseren Haarzellen mehr als 10 %* der inneren Haarzellen degeneriert, dann war der Hörverlust entsprechend schwerer und betrug bei Ausfall nahezu aller cochleären Haarzellen etwa 80 dB. Bei einigen Tieren war jedoch eine geringe Degeneration der *äusseren* Haarzellen nicht von einer entsprechenden Hörschwellenveränderung begleitet.

In der Cochlea von *12* Tieren wurden verhältnismässig abrupte Veränderungen der Hörschwelle beobachtet. Die nachfolgende histologische Untersuchung deckte korrespondierende, unterscheidbare Areale einer Haarzellenschädigung auf. Bei diesen 12 Tieren konnte die räumliche Anordnung der Frequenzlokalisation an der Basilarmembran analysiert werden.

1 INTRODUCTION AND PURPOSE OF THE STUDY

Thanks to antibiotics and chemotherapeutics, the prognosis of acute otitis media has improved considerably. Many of the complications which used to be common have become rare, and even when they occur they are seldom fatal. The improved therapeutic facilities for acute otitis media have been accompanied by a continuous fall in the incidence of chronic otitis media. This development has been favourable above all in districts where distances are not inconveniently long and where treatment at specialist level has been adequately available. The effectiveness of antibiotics and chemotherapeutics in acute otitis media is indisputable, but many find that excessive confidence in drug therapy as a universal panacea, and the omission of paracentesis in the treatment of acute otitis media, are the worst culprits in the development of a new middle ear problem: chronic secretory otitis media, and its high incidence in the last twenty years.

Politzer (1867) described the clinical picture of chronic secretory otitis media but in spite of this the condition has not been too well known among otologists even up to the last few years. The accumulation of glue-like secretion in the tympanum, which is typical of chronic secretory otitis media, may have passed unnoticed owing to the slightness of the symptoms. Furthermore, the resistance of the disease to therapy has produced poor therapeutic results. The etiology of the disease has been unclear, and due to the wide variety of therapeutic principles and the large number of therapeutic methods used, it has been difficult to make a comparison of the results. Not until Armstrong (1954) published his report on the use of a tympanostomy tube in the treatment of chronic secretory otitis media did the situation become considerably clearer, and with this method the therapeutic results have improved. The experimental, histological, histochemical and immunological studies of the last two decades have also thrown light on the etiology of the disease and created better conditions for successful treatment.

A number of sufficiently precise studies, with adequate follow up periods, have been reported in recent years concerning the effectiveness and complications of tympanostomy tube therapy (Mawson & Fagan, 1971; Kilby et al. 1972, Hussl, 1973b). However, the follow-up periods are, so far, still relatively short.

The purpose of the present study was to investigate, on the basis of clinical material,

- the clinical picture of chronic secretory otitis media, giving particular attention to the age at the onset of symptoms, to other concomitant diseases influencing the outbreak of the secretory otitis media, to the bacteriology of the middle ear effusion, and the possible complications of the disease,
- the required duration of tympanostomy tube therapy in chronic secretory otitis media, and the most frequent complications of this therapy
- the hearing loss in chronic secretory otitis media, the improvement of hearing produced by tube therapy, and the permanence of the improvement achieved.

2 REVIEW OF THE LITERATURE

2.1 CLINICAL PICTURE OF CHRONIC *SECRETORY OTITIS MEDIA*

Politzer (1867) was the first to describe the clinical picture of secretory otitis media, but even before his time there were in the literature reports on ear diseases which evidently referred to sectory otitis media (Wathen 1756 Cooper *1801)*

The most essential characteristic of secretory otitis media is middle ear effusion without the symptoms of infection accompanying acute otitis media. Acute secretory otitis media according to Tiedemann (1966) is a sequel to rhinopharyngitis and usually requires no particular therapy whereas chronic secretory otitis media according to Zöllner (1942) refers to those cases that have escaped early diagnosis and are of long duration

Senturia (1970) divided the middle ear effusions into serous seropurulent purulent mucopurulent and mucous According to him the protein content in the serous type was 11 4 g% in the purulent 7 7 g% and in the mucous 5 1 g% Usually the effusions in chronic secretory otitis media are divided into mucous and serous. According to Irstamm (1954) the effusion in children is usually mucous and viscous Sadé (1965) assumed that the serous effusion is derived from PAS negative and the mucous effusion from PAS-positive glands Palva et al. (1974b) studied the protein content of the mucous effusion in children s chronic secretory otitis media. In their material of 69 samples the mean protein content was 9 9 g% against 7 1 g% in the serum

Leegaard (1923) studied the causes of impaired hearing in school children and found that "Eustachian catarrh" was the cause in 24 7 % In a corresponding study by Lumio (1957) the share of chronic secretory otitis media was 52 % and in the material published by Justin (1958) 57 %

Chronic secretory otitis media is most common in children under 10 years of age and in most materials expressly in the 4—8-year olds (Hoople 1950 Armstrong 1957 Lenox 1962 Kersley & Wickham 1966 Draper 1967 Hussl 1973b) In Hussl s opinion the disease also occurs in younger children but is diagnosed less often since symptoms are slight. According to Watson (1969) impaired hearing in children was due to chronic secretory otitis media in 81 % of the 5-year olds but in 0 % of the 13-year olds On the basis of serial sections and direct middle ear measurements Holborow (1970) advanced the opinion that the opening mechanism of the Eustachian tube is not properly developed at birth and that the interval from birth to the 7th year of age is most critical period in view of the relative tubal insufficiency

In many materials chronic secretory otitis media is more common among boys than girls. Draper s (1967) series contained 61.2 % boys and 38 8 % girls. The distribution was much the same in the series reported by Eagle (1946), Stevens (1958) and Solow (1958) According to Solow this accords with the incidence of respiratory allergy among both sexes before puberty

In chronic secretory otitis media the appearance of the drum varies greatly Malcomson (1969) divided the drums into 18 groups on the basis of their appearance. Reduced mobility of the drum, when tested with Siegle s pneumatic speculum is considered one of the most reliable diagnostic signs (Davison 1958 Hussl 1973a) The final diagnosis can often not be made even with a microscope and

paracentesis may be the only means of verifying it (Hussl, 1973a)

The mean impairment of hearing in chronic secretory otitis media ranges in the different materials from 25 dB to 45 dB (Silverstein et al. 1966 Cohen & Sadé 1972, Kilby et al. 1972; Mawson & Fagan, 1972, Hussl 1973b) In the series of Cohen & Sadé and Mawson & Fagan the impairments followed Gauss's curve.

According to Dawes (1970) chronic secretory otitis media seldom leads to the development of adhesive otitis media. This agrees with the finding by Ojala (1953) that the development of chronic adhesive otitis media is preceded by recurrent infections exceeding a given minimum. According to Dawes, the most common conditions following chronic secretory otitis media include atrophy of the drum necrosis of the long process of the incus, disappearance of the superstructure of the stapes, and tympanosclerosis. Zafin (1963) claimed that chronic secretory otitis media is an intermediate phase in the development of cholesteatoma. In a material of 396 children who had had chronic secretory otitis media Zafin found pre-epidermosis at follow up examination in 17 % against an incidence of 3 % in the normal population. Jordan (1963) repord 11 cases in which cholesteatoma of the attic developed during the course of treatment for chronic secretory otitis media.

2.2. ETIOLOGY AND PATHOGENESIS

The etiology of secretory otitis media has long been unclear as evidenced also by the large number of synonyms used, serous otitis media, secretory otitis media, adhesive otitis media, otosalpingitis, tubotympanitis, hydrotympanum and glue ear although the disease is always the same.

There are two theories of the pathogenesis of secretory otitis media. the hydrops ex vacuo theory and the infection theory The hydrops ex vacuo theory which was the first to be evolved, was presented by Politzer (1867) and supported by his contemporaries Zaufal (1870) and Bezold (1883) According to this theory the cause of secretory otitis media is the hermetic closing of the Eustachian tube which results in the diffusion of middle ear gases into the blood vessels. The negative pressure then resulting in the middle ear produces a transudation of serum from the vessels into the tympanum. Such transudation has been found in connection with barotrauma but, according to van Dishoeck (1948) transudation presupposes a negative pressure of 150 cm H_2O while the maximum negative pressure measured in the middle ear has been 50—60 H_2O On the other hand, Flisberg et al. (1963) showed that a negative pressure of 20—30 mm Hg in the middle ear produced a bright yellow thin effusion in 15 minutes. In many animal experiments (Holmgren, 1940· Proud & Odoi, 1970· Paparella et al., 1970) this could be verified. Tönder & Gundersen (1971) also found support for the hydrops ex vacuo theory from their protein analyses of the middle ear effusion.

Brieger (1914) found that the Eustachian tube is hardly ever completely blocked in secretory otitis media and that the hydrops ex vacuo theory could not adequately account for the development of a middle ear effusion. In his opinion, the effusion was an exudate and was produced by an inflammatory process in the middle ear mucosa. This infection theory was supported by Kümmel (1914) Neuman (1930) Schlander (1932) Siirala & Lahikainen (1952) and Vuori (1959) Senturia, on the basis of numerous animal experiments, also came to the conclusion that secretory otitis media is of infectious origin (Senturia et al. 1958, 1960· Senturia, 1963 1970) In accordance with the infection theory the effusion in chronic secretory otitis media in many otologists opinion is bacterial (Forschner 1925 Biegvad, 1931 Senturia et al. 1958 Silverstein et al. 1966; Bernstein & Hayes, 1971) whereas the supporters of the hydrops ex vacuo theory claim that the effusion is sterile (Scheibe 1892, Jordan, 1949· Ivstamm 1954 Tönder & Gundersen, 1971) Of the 50 samples reported on by Bernstein & Hayes (1971) 60 % were sterile. The most common bacteria were *Hemophilus influenzae* *Streptococcus* and

2 REVIEW OF THE LITERATURE

2 1 CLINICAL PICTURE OF CHRONIC SECRETORY OTITIS MEDIA

Politzer (1867) was the first to describe the clinical picture of secretory otitis media but even before his time there were in the literature reports on ear diseases which evidently referred to sectory otitis media (Wathen 1756 Cooper 1801)

The most essential characteristic of secretory otitis media is middle ear effusion without the symptoms of infection accompanying acute otitis media Acute secretory otitis media, according to Tiedemann (1966) is a sequel to rhinopharyngitis and usually requires no particular therapy whereas chronic secretory otitis media, according to Zöllner (1942) refers to those cases that have escaped early diagnosis and are of long duration

Senturia (1970) divided the middle ear effusions into serous, seropurulent purulent, mucopurulent and mucous According to him the protein content in the serous type was 11 4 g% in the purulent 7 7 g% and in the mucous 5 1 g% Usually the effusions in chronic secretory otitis media are divided into mucous and serous According to Ivstamm (1954) the effusion in children is usually mucous and viscous Sadé (1965) assumed that the serous effusion is derived from PAS negative and the mucous effusion from PAS-positive glands Paiva et al (1974b) studied the protein content of the mucous effusion in children s chronic secretory otitis media In their material of 69 samples the mean protein content was 9 9 g% against 7 1 g% in the serum

Leegaard (1923) studied the causes of impaired hearing in school children and found that 'Eustachian catarrh" was the cause in 24 7 % In a corresponding study by Lumio (1957) the share of chronic secretory otitis media was 52 % and in the material published by Juselius (1958) 57 %

Chronic secretory otitis media is most common in children under 10 years of age and in most materials expressly in the 4—8-year olds (Hoople 1950 Armstrong 1957 Lemon 1962, Kersley & Wickham 1966 Draper 1967 Hussl 1973b) In Hussl's opinion the disease also occurs in younger children but is diagnosed less often since symptoms are slight. According to Watson (1969) impaired hearing in children was due to chronic secretory otitis media in 81 % of the 5-year olds but in 0 % of the 13-year olds On the basis of serial sections and direct middle ear measurements Holborow (1970) advanced the opinion that the opening mechanism of the Eustachian tube is not properly developed at birth and that the interval from birth to the 7th year of age is most critical period in view of the relative tubal insufficiency

In many materials chronic secretory otitis media is more common among boys than girls Draper s (1967) series contained 61 2 % boys and 38 8 % girls. The distribution was much the same in the series reported by Eagle (1946) Stevens (1958) and Solow (1958) According to Solow this accords with the incidence of respiratory allergy among both sexes before puberty

In chronic secretory otitis media the appearance of the drum varies greatly Malcomson (1969) divided the drums into 18 groups on the basis of their appearance. Reduced mobility of the drum when tested with Siegle s pneumatic speculum is considered one of the most reliable diagnostic signs (Davison 1958 Hussl 1973a) The final diagnosis can often not be made even with a microscope and

carried no mucus-secreting elements. According to them serous effusion is transudate, and a result of increased capillary permeability.

On the basis of protein and enzyme analyses of the middle ear effusions, Palva et al. (1974a, 1974b) claim that the middle ear effusion cannot be transudate but it must be a result of active secretion. In their studies, the middle ear effusion showed considerably higher levels of lactate and malate dehydrogenase, acid phosphatase, aspartate aminotransferase and alanine aminotransferase than the serum. On the other hand the alkaline phosphatase levels were equally high in the serum and middle ear effusion, while the nonspecific esterase level in the serum was higher than the middle ear effusion.

Most otologists are agreed that adenoids sinusitis, nasopharyngeal infections and cicatricial changes of the tubal orifice play a part in the etiology of chronic secretory otitis media.

Despons (1958) reported that there is, in the Eustachian tube near the pharyngeal orifice a so-called tubal tonsil which plays a part in the etiology of the disease, but Aschan (1955) was unable to verify from histological sections any lymphatic tissue in the tube.

The role of allergy in the etiology of chronic secretory otitis media has been variously described. According to Dohlman (1943) allergy was the cause in a number of cases. Jordan (1949) attributed the disease to allergy in 74 % and in a later material (1952) in no less than 87 % of the cases. Lecks (1961) quoted equally high percentages. According to Draper (1967) allergic children had an incidence of secretory otitis media twice that of non-allergic children. In the other materials published, the share of allergy has been considerably lower (Hotchkiss, 1948 Suehs, 1952· Stevens, 1958, Lemon, 1962 Silverstein et al., 1966; Kersley & Wickham, 1966) Wright & Kapadia (1969) failed to find eosinophils in the middle ear effusion of any of the patients in their material.

Cleft palate patients have been found to have a remarkably high incidence of chronic secretory otitis media. It has long been known that impaired hearing is very common among the cleft palate patients (Sataloff & Fraser 1952, Holmes & Reed 1955 Halfond & Ballenger 1956, Skolnik, 1958 Masters et al., 1960· Holborow 1962, Graham & Lierle, 1962, Aschan 1966) but Stool & Randall (1967) were the first to show that it was mainly due to chronic secretory otitis media. In materials published later nearly 100 % of the cleft palate cases have had chronic secretory otitis media (Paradise & Bluestone, 1969· Paradise et al 1969) According to Holborow (1970) the cause of secretory otitis in cleft palate patients is the impaired function of the musculus tensor veli palatini and the resulting dysfunction of the Eustachian tube

Other causes of chronic secretory otitis media have also been suggested. Hopp et al. (1964) gave immunization as a possible cause· in their experiments with guinea pigs immunized with bovine serum albumin they managed to bring about a clinical picture reminiscent of secretory otitis media. Davison (1958) also listed systemic factors such as obesity and hypothyroidism among the possible causes.

Many otologists are of the opinion that the incidence of chronic secretory otitis media has increased considerably during the era of antibiotics, and attribute this to an inadequate administration of the antibiotics and the omission of paracentesis in the treatment of acute otitis media (Suehs, 1956· Armstrong 1957 Davison, 1958, Friedmann, 1963 Palva et al. 1974a, 1974b)

2.3 TREATMENT AND ITS RESULTS

Most otologists have observed the ineffectiveness of paracentesis and myringotomy in the treatment of chronic secretory otitis media, although Senturia et al. (1960) were of the opinion that weekly paracentesis under general anaesthesia sufficed in most cases. Attempts to improve the effectiveness of paracentesis have been made by making several incisions (Lemon 1962, Kersley & Wickham, 1966) or by combining it with retrograde tubal inflation, but the latter has been reported to have produced lethal complications (Åhren & Thulin, 1965

Pneumococcus. Bacteriological sterility has also been attributed to viral etiology Berglund et al (1966) managed to isolate RS viruses from the middle ear effusion in acute otitis media Siirala (1957) attributed bacteriological sterility to the bactericidal and bacteriostatic effect of the middle ear effusion which he had previously verified in acute otitis media (Siirala & Lahikainen 1952) It has been proved later that this effect is derived from the IgA secreted by the mucous glands (Bernstein et al 1973)

While most authors are of the opinion that complete blockage of the Eustachian tube in secretory otitis media has not been demonstrated, they are unanimous that there must be a relative dysfunction of the Eustachian tube Sato (1939) showed with animal experiments that the normal ciliary movement quickly removed foreign particles from the tympanum The same result was reported by Compere (1958) who examined the tubal function with water soluble contrast medium When the tubal function was normal the contrast medium introduced into the tympanum through the eardrum disappeared in a matter of minutes, whereas in chronic secretory otitis media there were a few cases when the tympanum was never cleared although tubal inflation was relatively easy A similar result was reported by Rogers et al (1962) who studied the tubal function in dry and moist perforated ears with fluorescence techniques Westergaard (1970) examined the tubal function tympanometrically with Flisberg s aspiration techniques. None of 18 children with chronic secretory otitis media all with tympanostomy tubes in position was able to reduce negative pressures in any phase of the treatment whereas immediately after insertion of the tubes, 54 % of the patients and after 6 months of treatment 76 % could reduce positive pressures. A similar finding was reported by Silverstein et al (1966)

Sadé (1965 1966a 1966b 1967 Sadé & Weinberg 1969) has extensively described the histology of the mucosa of the normal middle ear and of one affected with secretory otitis media According to Sadé the mucosa of the healthy middle ear at the orifice of the tube is pseudostratified columnar and ciliated, and further back in the tympanum it has a columnar cuboidal or flat-cell structure He reports that ciliated epithelium extends in the normal middle ear from the tubal orifice over c. one-third to two-thirds of the tympanal mucosa but normally not to the antrum to mastoid air cells and the medial surface of the eardrum According to Sadé the rate of ciliary movement in dry perforated ears is 1—1.5 mm/sec whereas in moist perforated ears the movement is slower or none Secreting elements are situated in areas with ciliated epithelium and according to Sadé secretory otitis media involves either a hypersecretion of mucus or an impairment of ciliary function Lim & Hussl (1969) found ciliated epithelium also in the antrum mastoid air cells and the medial surface of the eardrum They reported two types of secreting cells on the mucosa of the healthy middle ear goblet cells and intermediate cells. Lim et al (1973) found with electron microscopy that the distribution of mucus-secreting cells was the same as that of ciliated cells.

Friedmann (1963) found that in guinea pigs, infection produced a heavy increase in the goblet cells and glandular elements of the columnar epithelium within a fortnight Friedmann attributed the chronicity of secretory otitis media to the accumulation of mucus caused by the mucosal changes regardless of whether the tube was patent or not

Tos & Bak Pedersen (1972 1973 Bak Pedersen & Tos, 1971 1973) studied the incidence of glands on the middle ear mucosa in different pathological conditions They reported that the density of mucous glands on the middle ear mucosa in secretory otitis media was 7 1/mm² in chronic otitis media 3 4/mm² in otosclerosis 1 7/mm² and in tympanosclerosis 0 6/mm² Furthermore in secretory otitis media 90 % of the glands were active against only 0—20 % in the rest of the above diseases

In their electron microscope studies Lim & Birck (1971) found a high rate of mucus secreting elements from mucosal biopsies taken from middle ears with mucous secretion whereas in serous otitis media the mucosa

carried no mucus-secreting elements. According to them, serous effusion is transudate and a result of increased capillary permeability.

On the basis of protein and enzyme analyses of the middle ear effusions, Palva et al. (1974a, 1974b) claim that the middle ear effusion cannot be transudate but it must be a result of active secretion. In their studies, the middle ear effusion showed considerably higher levels of lactate and malate dehydrogenase, acid phosphatase, aspartate aminotransferase and alanine aminotransferase than the serum. On the other hand, the alkaline phosphatase levels were equally high in the serum and middle ear effusion, while the nonspecific esterase level in the serum was higher than the middle ear effusion.

Most otologists are agreed that adenoids, sinusitis, nasopharyngeal infections and cicatricial changes of the tubal orifice play a part in the etiology of chronic secretory otitis media.

Despons (1958) reported that there is, in the Eustachian tube near the pharyngeal orifice, a so-called tubal tonsil which plays a part in the etiology of the disease, but Aschan (1956) was unable to verify from histological sections any lymphatic tissue in the tube.

The role of allergy in the etiology of chronic secretory otitis media has been variously described. According to Dohlman (1943) allergy was the cause in a number of cases. Jordan (1949) attributed the disease to allergy in 74 % and in a later material (1952) in no less than 87 % of the cases. Lecks (1961) quoted equally high percentages. According to Draper (1967) allergic children had an incidence of secretory otitis media twice that of non-allergic children. In the other materials published, the share of allergy has been considerably lower (Hotchkiss, 1948, Suehs, 1952, Stevens, 1958, Lemon, 1962, Silverstein et al. 1966, Kersley & Wickham, 1966). Wright & Kapadia (1969) failed to find eosinophils in the middle ear effusion of any of the patients in their material.

Cleft palate patients have been found to have a remarkably high incidence of chronic secretory otitis media. It has long been known that impaired hearing is very common among the cleft palate patients (Sataloff & Fraser, 1952, Holmes & Reed, 1955, Halfond & Ballenger, 1956; Skolnik, 1958, Masters et al. 1960, Holborow, 1962, Graham & Lierle, 1962, Aschan, 1966) but Stool & Randall (1967) were the first to show that it was mainly due to chronic secretory otitis media. In materials published later nearly 100 % of the cleft palate cases have had chronic secretory otitis media (Paradise & Bluestone, 1969, Paradise et al. 1969). According to Holborow (1970) the cause of secretory otitis in cleft palate patients is the impaired function of the musculus tensor veli palatini and the resulting dysfunction of the Eustachian tube.

Other causes of chronic secretory otitis media have also been suggested. Hopp et al. (1964) gave immunization as a possible cause: in their experiments with guinea pigs immunized with bovine serum albumin they managed to bring about a clinical picture reminiscent of secretory otitis media. Davison (1958) also listed systemic factors such as obesity and hypothyroidism among the possible causes.

Many otologists are of the opinion that the incidence of chronic secretory otitis media has increased considerably during the era of antibiotics, and attribute this to an inadequate administration of the antibiotics and the omission of paracentesis in the treatment of acute otitis media (Suehs, 1956, Armstrong, 1957, Davison, 1958, Friedmann, 1963, Palva et al. 1974a, 1974b).

2.3. TREATMENT AND ITS RESULTS

Most otologists have observed the ineffectiveness of paracentesis and myringotomy in the treatment of chronic secretory otitis media, although Senturia et al. (1960) were of the opinion that weekly paracentesis under general anaesthesia sufficed in most cases. Attempts to improve the effectiveness of paracentesis have been made by making several incisions (Lemon, 1962; Kersley & Wickham, 1966) or by combining it with retrograde tubal inflation, but the latter has been reported to have produced lethal complications (Åhren & Thulin, 1965,

Fairman et al 1968) Tubal catheterization and Valsalva s manoeuvre were earlier in general use but Hussl (1973b) pointed out that they alone did not lead to the desired result.

Adenotomy and treatment of the nasal and nasopharyngeal infections cure a large proportion of the chronic secretory otitis media according to Lemon (1962) and Gottschalk (1972) *whereas Mawson & Fagan (1972) find* that "adenoidectomy as a primary form of treatment has no justification

Many others methods of treatment were formerly used for chronic secretory otitis media such as nasopharyngeal irradiation (Adams 1956 Suehs 1956 Aschan & Nohrmann 1957) destruction of lymphatic tissue at the tubal orifice with trichloracetic acid brushing (Ivstamm 1954) removal of hyperplastic tonsils (Malcomson 1969) antiallergic therapy (Jordan 1949) systemic (Oppenheimer 1968) or local (Torrey 1971) steroid therapy alpha chymotrypsin treatment to reduce the viscosity of the effusion (Kersley & Wickham 1966) irradiation of the Eustachian tube (Beck, 1969) exhairesis of the Jakobson nerve (Malcomson 1969) *tympanotomy to remove the tenacious* effusion (Mawson & Brennand 1969) Mastoidectomy has been recommended for the treatment of cases *resistant to therapy* (Davison 1958 *Stevens, 1962 Grahne 1964*)

According to Politzer (1878) persistent perforation was considered desirable already in the 17th century in the treatment of ear diseases without any definite indications but Himly and Cooper (1801) were the first to try permanent perforations in the therapeutic sense

Politzer himself treated secretory otitis media with excision of a part of the drum sphirotomy incisions and lapis coagulation of wound edges corrosion of perforations with sulphuric acid and galvanocautery but *failed to obtain permanent* results. He tried to keep the perforations open by *inserting a small rubber tube*, but the tubes were too quickly extruded just as were the silver cannulas of Bonnafont and the aluminium tubes of Voltolini two of his contemporaries. Hotchkiss (1948) tried to produce persistent perforations by a corneal trephine but his results were also *unsatisfactory* Armstrong (1954) was the first who managed to ventilate the tympanum for several months by means of vinyl tubes. In recent years the tympanostomy tubes have gained extensive popularity in the *treatment of chronic secretory* otitis media, several tube types have been designed and many materials have been used (*Lindeman & Silverstein 1964 Schmidt &* Bolhuis, 1965 Silverstein 1965 Feuerstein 1966 Turner 1967 Wilson 1969)

Until the last few years the therapeutic results have been difficult to compare since the therapeutic indications and methods have been extremely varied and the follow up period in many materials have been inadequate.

Stevens (1962) invited 53 children, whom he had treated for "serous otitis media" 5—7 years *previously to come for a follow up examination.* 32 children attended the examination. Drum changes were seen in 79 % of the ears, and in 33 % the changes were of a severe degree Three *ears had an adhesive drum and one a* posterosuperior perforation and cholesteatoma. Five ears were still affected with serous otitis media" On the whole the changes were more severe in the ears in which the effusion had originally been thicker

Gottschalk (1972) reported good results with *the conservative treatment of a material of 182* patients (258 ears) On admission the patients were first subjected to a meticulous adenoidectomy reaching to the fascia, and at the same time two myringotomy orifices were made to remove the effusion as completely as possible. There was an immediate relapse in only 8 ears. Within 12 months the disease had not recurred in 68 % of the re-examined ears (200 ears) Paracentesis had been made in only 2 ears after the institution of therapy· all others had healed with drugs In *Gottschalk s opinion when the disease recurred* weeks or months later this was not a therapeutic failure but a new onset of the disease This view explains the good results reported.

In recent years several reports have been published on the results of tympanotomy tube therapy Neveling (1968) reported good hearing results in all subjects of his material of 84

12 9 % later in the course of the tube treatment. All infections healed without complications In only one drum was a perforation left after extrusion of the tube The tympanostomy tube had to be inserted twice in 20 2 % and three or more times in 3 2 % Preoperatively the hearing level within the speech frequencies in the total material was 40 dB (mean of 500 1000 and 2000 Hz) and immediately after tube insertion 10 dB 114 ears were re-examined 6—24 months after the insertion 45 6 % of the drums were normal 26.3 % showed retraction of pars tensa 11 4 % had tympanosclerosis and 10 4 % atrophic scars or an atrophic posterosuperior quadrant. One drum was found to have a persistent perforation and one ear developed mastoiditis nigra which was treated with mastoidectomy and tympanotomy No instance of complete adhesive otitis media was noted but one of the drums adhered to the head of the stapes. No cholesteatoma was found at the follow up examination In 5 ears the tube was in position at this examination

In the materials described above drum changes following the tympanostomy tube therapy were common and increased as a function of the duration of the therapy (Mawson & Fagan 1972 Kilby et al 1972, Hussl 1973b) In the material of Mawson & Fagan, 40 % of the drums and Hussl s material 45.6 % were normal at the follow up examination 6—60 months after the insertion of the tube. The most common changes were tympanosclerosis and retraction of the drum According to Mawson & Fagan drum changes are not necessarily combined with impaired hearing Both materials contained only one persistent perforation each. Mawson & Fagan s material contained one posterosuperior perforation and cholesteatoma, but there was no instance of attic cholesteatoma in either material although Jordan (1963) reported 11 cases in connection with the treatment of chronic secretory otitis media. The recurrence rate in Mawson & Fagan s material was 10 % much the same as the rates quoted by Lemon (1962) Schuknecht et al. (1964), Schmidt & Bolhuis (1965) and Feuerstein (1966) The hearing results in the above materials were very different. The results, almost 100 % good reported by Neveling (1968) and Tarab (1969) apparently referred to the time immediately after insertion of the tube and are therefore not comparable as such with the late results In the late results reported by Mawson & Fagan the hearing level in 65 % of the ears was better than 20 dB and in 9 % poorer than 30 dB.

3 MATERIAL

The material comprised all patients under 15 years of age treated in 1965—71 for chronic secretory otitis media in the wards of the Department of Otolaryngology of Oulu University a total of 181 children (Table I) All these patients had undergone repeatedly paracentesis which had yielded glue-like secretion. In 142 patients the affection was bilateral, in 39 unilateral, and the total number of ears treated was 323 (Table II) There were 106 boys (59 %) and 75 girls (41 %)

164 patients were treated by inserting a tympanostomy tube into 290 ears, and 17 patients, total 33 ears, by repeated paracentesis (Table II) The number of the cases treated had increased continuously year by year In 1965—66 only 2 children were treated in the wards for chronic secretory otitis media, but by 1971 the figure had risen to 53 children (Table I)

The material came from a district which, in 1965 covered an area of 130 000 km and had 550,000 inhabitants, and where the longest distances to the hospital were c. 500 km. In 1971 after the construction of new hospitals, the area of the hospital district was 30,000 km with 260,000 inhabitants, and the maximum distance to the hospital was c. 250 km.

The majority of the patients had, before admission, been treated by general practitioners, and the treatment had consisted of repeated paracentesis and courses of antibiotics.

Table I. *The number of fresh cases treated annually*

Year	No. of patients
1965	1
1966	1
1967	22
1968	21
1969	40
1970	43
1971	53
Total	181

On their first admission to the hospital, the patients underwent a normal otological examination which additionally included a myringotomy and the aspiration of a sample for bacterial culture, radiography of the ear and sinuses, and an audiometric hearing test. Where necessary the part possibly played by allergy was also investigated. Tympanostomy tubes were inserted as a primary treatment in a small number of patients. In most cases, however the patient first underwent adenotomy and was then seen weekly or fortnightly tubes being inserted later if the disease did not heal. A number of patients only underwent adenotomy or adenotonsillectomy without tympanostomy tubes.

Table II. *Distribution of the series by mode of treatment and sex*

Mode of treatment	No. of patients							Total no. of ears
	female	(%)	male	(%)	unilat.	bilat.	total	
Tympanostomy	68	(41)	96	(59)	38	126	164	290
No tympanostomy	7	(41)	10	(59)	1	16	17	33
Total	75	(41)	106	(59)	39	142	181	323

12 9 % later in the course of the tube treatment. All infections healed without complications In only one drum was a perforation left after extrusion of the tube The tympanostomy tube had to be inserted twice in 20 2 % and three or more times in 3 2 % Preoperatively the hearing level within the speech frequencies in the total material was 40 dB (mean of 500 1000 and 2000 Hz) and immediately after tube insertion 10 dB 114 ears were re-examined 6—24 months after the insertion. 45 6 % of the drums were normal 26 3 % showed retraction of pars tensa, 11 4 % had tympanosclerosis and 10 4 % atrophic scars or an atrophic posterosuperior quadrant. One drum was found to have a persistent perforation and one ear developed mastoiditis nigra which was treated with mastoidectomy and tympanotomy No instance of complete adhesive otitis media was noted but one of the drums adhered to the head of the stapes No cholesteatoma was found at the follow up examination In 5 ears the tube was in position at this examination

In the materials described above drum changes following the tympanostomy tube therapy were common and increased as a function of the duration of the therapy (Mawson & Fagan 1972 Kilby et al. 1972 Hussl 1973b) In the material of Mawson & Fagan, 4 % of the drums and Hussl s material 45 6 % were normal at the follow-up examination 6—(months after the insertion of the tube. The mo common changes were tympanosclerosis an retraction of the drum According to Mawson Fagan drum changes are not necessari combined with impaired hearing Both materi contained only one persistent perforation eac Mawson & Fagan s material contained o posterosuperior perforation and cholesteatom but there was no instance of attic cholesteatom in either material although Jordan (196 reported 11 cases in connection with t treatment of chronic secretory otitis media. Th recurrence rate in Mawson & Fagan s materi was 10 % much the same as the rates quoted l Lemon (1962) Schuknecht et al. (1964 Schmidt & Bolhuis (1965) and Feuerste (1966) The hearing results in the abo materials were very different. The result almost 100 % good, reported by Neveling (196 and Tarab (1969) apparently referred to the tim immediately after insertion of the tube and a therefore not comparable as such with the la results. In the late results reported by Mawson Fagan the hearing level in 65 % of the ears w better than 20 dB and in 9 % poorer than 30 dl

3 MATERIAL

The material comprised *all* patients under 15 years of age treated in 1965—71 for chronic secretory otitis media in the wards of the Department of Otolaryngology of Oulu University a total of 181 children (Table I) All these patients had undergone repeatedly paracentesis which had yielded glue-like secretion. In 142 patients the affection was bilateral, in 39 unilateral, and the total number of ears treated was *323 (Table II)* *There were 106 boys* (59 %) and 75 girls (41 %)

164 patients were treated by inserting a tympanostomy tube into 290 ears, and 17 patients, total 33 ears, by repeated paracentesis (Table II) The number of the cases treated had increased continuously year by year In 1965—66 only 2 children were treated in the wards for chronic secretory otitis media, but by 1971 the figure had risen to 53 children (Table I)

The material came from a district which, in 1965 covered an area of 130,000 km and had 550,000 inhabitants, and where the longest distances to the hospital were c. 500 km. In 1971 after the construction of new hospitals, the area of the hospital district was 30,000 km with 260,000 inhabitants, and the maximum distance to the hospital was c. 250 km.

The majority of the patients had, before admission, been treated by general practitioners, and the treatment had consisted of repeated paracentesis and courses of antibiotics.

Table I. *The number of fresh cases treated annually*

Year	No. of patients
1965	1
1966	1
1967	22
1968	21
1969	40
1970	43
1971	53
Total	181

On their first admission to the hospital, the patients underwent a normal otological examination which additionally included a myringotomy and the aspiration of a sample for bacterial culture, radiography of the ear and sinuses, and an audiometric hearing test. Where necessary the part possibly played by allergy was also investigated. Tympanostomy tubes were inserted as a primary treatment in a small number of patients. In most cases, however the patient first underwent *adenotomy* and was then seen weekly or fortnightly tubes being inserted later if the disease did not heal. A number of patients only underwent adenotomy or adenotonsillectomy without tympanostomy tubes.

Table II. *Distribution of the series by mode of treatment and sex*

Mode of treatment	No. of patients							Total no. of ears

Total	75	(41)	106	(59)	39	142	181	323

Fig 1 The models of tympanostomy tube used. Right, a self made tube of polyethylene (PE 100) and left the silastic tube (Donaldson)

Tubes were inserted under general anaesthesia by young resident surgeons. In most cases *self made polyethylene (PE 100) tubes* and in a smaller group commercial silicone tubes, were used Before the insertion the external meatus was cleaned mechanically only The paracentesis was usually made in the anteroinferior quadrant of the drum but if this was technically difficult in the posteroinferior quadrant. In some cases of long duration in which the inferior part of the drum was atrophic, the tube was placed in the anterosuperior quadrant within the normal drum area. After the effusion had been aspirated, the tube was placed in the para centesis aperture with very small straight alligator forceps, under microscopic control With some experience the prosedure lasted only a few minutes.

Subsequently the patient was usually given a 7 day course of antibiotics. He then visited the outpatient clinic first at monthly intervals and later at intervals of 2—3 months Possible crusts around the tube were removed, their openness was assured and an audiometric hearing test carried out If chronic secretory otitis media recurred after the extrusion of the tube, another tube was inserted

The tubed patients or their parents were instructed not to let water get into the tubed ears. The patients were allowed to take a bath in a bath tub or sauna and to swim if they put cotton wool moistened in paraffin into the external meatus but they were not allowed to dive All respiratory infections were treated carefully The patients parents were requested to get in touch with the treating physician immediately if there was any discharge. The discharge was removed by syringing the ear with physiological saline ear drops were used locally and antibiotics orally

Data on the patients medical history on their period of hospitalization and outpatient clinic visits were obtained from case histories, and complemented if necessary in connection with the follow up examination This was carried out during the autumn of 1972, all the 181 patients of the material being invited with an attendance of 166 (91 6 %) On this occasion the present author personally carried out the otological examination of all patients using the operating microscope to help in ascertaining the drum status. At the same time an audiometric hearing test for air and bone conduction was carried out on all patients over 4 years of age Due to poor cooperation the hearing results of a number of the youngest patients were unreliable and had to be excluded from the statistical analyses. The audiometric test was carried out by the two trained examiners who had made the earlier audiometric tests. All hearing level examinations were made with the Madsen Model OB 70 audiometer calibrated according to the ISO standards The results were analysed at the Oulu University Computer Centre Student s t test was used for the statistical comparison of the results

4 RESULTS

4.1 CLINICAL DATA

4.1.1 The tympanostomy group

The chronic secretory otitis media of 164 children, 96 boys (59 %) and 68 girls (41 %) was treated by inserting tympanostomy tubes into a total of 290 ears. In 126 children 73 boys (58 %) and 53 girls (42 %) the disease was bilateral, and in 38 children, 23 boys (61 %) and 15 girls (39 %) it was unilateral (Table II)

4.1.1.1 Preoperative history and data from the time of treatment

In the 38 children with unilateral disease the other ear was healthy in 30 cases. In 2 patients the contralateral ear had been treated with mastoidectomy for chronic suppurative otitis media, in 2 ears a cholesteatoma and in 2 a dry drum perforation had been diagnosed, and another 2 ears were affected with chronic secretory otitis media which healed with paracenteses.

Half of the patients had, or had previously had, other diseases (Table III) Congenital cleft palates were operated on, at the latest in connection with the tube treatment. Two of the 5 mentally retarded children apparently were congenitally deaf. Perceptive hearing defects, of unknown etiology were bilateral.

One patient with bilateral chronic secretory otitis media had become deaf in one ear following paracentesis carried out by a general practitioner

104 children had previously had suppurative otitis media, while 60 children had no previous ear history Purulent discharge from the ear had occurred in 30 children.

The onset of the symptoms of secretory otitis media had usually occurred before school age (Table IV) The biggest age group consisted of

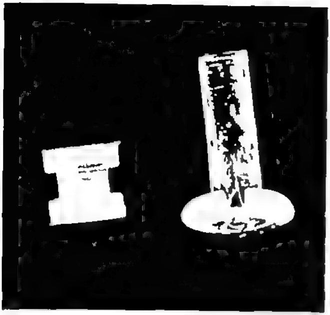

Fig 1 The models of tympanostomy tube used. Right, a self made tube of polyethylene (PE 100) and left, the silastic tube (Donaldson)

Tubes were inserted under general anaesthesia by young resident surgeons In most cases self made polyethylene (PE 100) tubes and in a smaller group commercial silicone tubes were used Before the insertion the external meatus was cleaned mechanically only The paracentesis was usually made in the anteroinferior quadrant of the drum but if this was technically difficult, in the posteroinferior quadrant In some cases of long duration in which the inferior part of the drum was atrophic the tube was placed in the anterosuperior quadrant within the normal drum area. After the effusion had been aspirated the tube was placed in the para centesis aperture with very small straight alligator forceps, under microscopic control With some experience, the prosedure lasted only a few minutes.

Subsequently the patient was usually given a 7-day course of antibiotics He then visited the outpatient clinic first at monthly intervals and later at intervals of 2—3 months Possible crusts around the tube were removed, their openness was assured and an audiometric hearing test carried out. If chronic secretory otitis media recurred after the extrusion of the tube, another tube was inserted.

The tubed patients or their parents were instructed not to let water get into the tubed ears. The patients were allowed to take a bath in a bath tub or sauna and to swim if they put cotton wool moistened in paraffin into the external meatus, but they were not allowed to dive. All respiratory infections were treated carefully The patients parents were requested to get in touch with the treating physician immediately if there was any discharge. The discharge was removed by syringing the ear with physiological saline ear drops were used locally and antibiotics orally

Data on the patients medical history on their period of hospitalization and outpatient clinic visits were obtained from case histories, and complemented if necessary in connection with the follow up examination This was carried out during the autumn of 1972 all the 181 patients of the material being invited with an attendance of 166 (91 6 %) On this occasion the present author personally carried out the otological examination of all patients using the operating microscope to help in ascertaining the drum status At the same time an audiometric hearing test for air and bone conduction was carried out on all patients over 4 years of age. Due to poor cooperation the hearing results of a number of the youngest patients were unreliable and had to be excluded from the statistical analyses The audiometric test was carried out by the two trained examiners who had made the earlier audiometric tests. All hearing level examinations were made with the Madsen Model OB 60 audiometer calibrated according to the ISO standards The results were analysed at the Oulu University Computer Centre Student s t test was used for the statistical comparison of the results.

Purulent discharge occurred during tube treatment in 124 cases (25 %) i.e. 118 ears (41 %) and 79 patients (48 %). When the bacterial culture on tube insertion was positive, discharge occurred in 55 % of the cases, and when Hemophilus influenzae grew in the bacterial culture discharge occurred in 79 % of the cases. The most common bacteria were Staphylococcus aureus (37.4 %), Diplococcus pneumoniae (12.5 %), Hemophilus influenzae (11.7 %), Staphylococcus albus (8.9 %), Escherichia coli (6.1 %), Streptococcus (5.6 %) and Pseudomonas aeruginosa (5.0 %).

4.1.1.2. Follow up study

The follow-up examination was attended by 151 patients. Four patients reported by letter that their ears were symptom-free and the hearing level, in an audiometric examination at school, had been found to be normal. Their tympanostomy tubes had been extruded, and their follow up period exceeded 2 years. Information concerning them was obtained from the record of the last visit to the outpatient clinic. Nothing was heard concerning 9 patients, who also had an outpatient follow-up period exceeding 2 years and whose tympanostomy tubes had been extruded. The information concerning them was also taken from the record of the last visit to the outpatient clinic.

The average follow-up period was 3 years 2 months (range 12 months to 7 years). During this period the tube had been removed from 19 ears after 4—6 months of treatment. In 3 of these ears, a recurrence developed within the next 6 months. In all the other patients, the tubes were allowed to extrude spontaneously and if the disease recurred a new one was inserted. Mastoidectomy was carried out during the follow-up period on 8 patients representing 15 ears for persistent discharge and on the basis of the x-ray finding. In one of these ears the discharge started immediately on insertion of the tube. At operation, the mastoid air cells of 5 ears were found to be filled with glue-like secretion. In 2 ears the mucosa of the mastoid air cells was thickened, and in 8 ears the mucosa was granulative and new bone formation was visible. After mastoidectomy there was no discharge from 4 ears, and discharge of short duration from 9 ears, but in one patient who had ozaena also, discharge was almost continuous from both ears. At the follow up the drum was normal in 10 ears, the tube still remained in 4 ears, and perforation with discharge was seen in one ear (ozaena).

The follow up showed that chronic secretory otitis media had healed completely in 190 ears (65.5 %). No tubes were left in these ears, and no signs of recurrence were observed (Table VI). Altogether chronic secretory otitis media had healed in 100 patients (69.8 %), in 68 of whom it had healed in both ears, in 22 in only one ear and in 32 in the single ear affected. The mean duration of tympanostomy tube therapy in the ears, which were found to be healthy at the time of the examination, was 11.3 months (range 1 month to 5 years) and the mean symptom free period after healing was 19 months (range 1 month to 5 years).

Table VI. *Status at the follow-up examination of the ears treated with tympanostomy*

Status at the follow-up examination	No.	%
Chronic secretory otitis media healed	190	65.5
Tympanostomy tubes in position and ventilating	64	22.1
Purulent discharge from tympanostomy tube	5	1.7
Chronic secretory otitis media recurred	9	3.1
Complications of chronic secretory otitis media and tube therapy	22	7.6
Total	290	100.0

In the ears in which chronic secretory otitis media had healed, the *appearance* of the drum was normal or nearly normal in 130 cases (68.4 %) and abnormal in 60 cases (31.6 %) (Table VII). The appearance of the drum was classified as normal if no abnormality could be observed on examination with Siegle's pneumatic speculum. The pathological drums were divided into subgroups on the basis of their microscopic appearance. The tympanostomy scar was visible

children under 1 year (18.9 %) but that of the 7—8 year olds i.e those who had just started school was almost as big (14 6 %) The mean age of onset was 4 years 10 months.

Adenotomy had been carried out earlier on 48 patients and adenotonsillectomy on 14 In the course of the treatment of chronic secretory otitis media adenotomy was performed on 129 and adenotonsillectomy on 15 patients 52 of the adenotomies were re-adenotomies No operation was made on 10 patients, 8 of whom had cleft palate one ozaena, and in one patient aged 14 years no adenoid tissue was present

On admission to hospital 24 children were found to have sinusitis and 4 allergic rhinitis There was no instance of hypo- or agamma globulinaemia but in 9 children the immunoglobulin values were at the lower limit of normal

An abnormal status of the nasopharynx was seen in 6 patients. In 2 of these the tubal orifices were severely strictured after an earlier adenotomy and in another 2 the orifices were otherwise very narrow One patient after adenotomy had developed a synechia from the soft palate to the roof of the nasopharynx and in another the tori were hypertrophic, practically filling the nasopharynx Very large-sized adenoids were found in 35 children

The mean interval from the diagnosis of secretory otitis media to the insertion of tympanostomy tubes was 8.5 months. In this interval a number of the patients were treated by weekly paracentesis, while others were symptom free for months of even years in the meantime The mean age of the patients at the time of the first insertion of tubes was 5 years 8 months The tube was inserted only once into 169 ears (58 3 %) twice into 62 ears (21 4 %) three times into 34 ears (11 7 %) and four or more times into 25 ears (8 6 %) The highest number of tympanostomy tubes per ear was 8 of which 7 were inserted in another hospital. All told 511 tubes were inserted to the patients of the present series The mean period during which the tubes remained ventilating was 7 0 months The first tube remained in position for 7 8 months on average the second for 7 2 months the third for 6 3 months and from the fourth onwards for 6 0 months The shortest period was 48 hours after which the tube was extruded with purulent discharge and the longest 56 months. Tympanotomy had to be carried out twice after the inserted tube had slipped into the tympanum. Both ears healed without complications.

In the preliminary examinations a sample was taken in connection with paracentesis for bacterial analysis The cultures of these samples were always negative in 74 ears (25.5 %) None of these patients had been treated with antibiotics immediately before paracentesis

In connection with the insertion of the tympanostomy tube a bacterial sample was taken under operating-microscope control direct from the paracentesis opening The external meatus was only mechanically cleaned before the procedure. A total of 322 bacterial samples (198 ears) were taken in connection with 511 tube insertions. The bacterial culture of 251 samples (78 %) was negative and that of 71 samples (22 %) positive. The most common bacteria were Hemophilus influenzae Staphylococcus aureus and Staphylococcus albus (Table V)

Table V *Results of bacterial analysis of samples taken in connection with insertion of the tubes*

Organism	No	% of positive cultures
Hemophilus influenzae	19	26.8
Staphylococcus aureus	14	19 9
Staphylococcus albus	14	19 9
Diplococcus pneumoniae	6	8.4
Klebsiella pneumoniae	4	5.6
Neisseria catarrhalis	4	5 6
Pseudomonas aeruginosa	4	5 6
Aerobacter aerogenes	1	1 4
Alkaligenes faecalis	1	1 4
Escherichia coli	1	1 4
Hafnia	1	1 4
Corynebacterium pseudodifteriae	1	1 4
Candida	1	1 4
Total positive cultures	71	
Negative cultures	251	
Total analyses	322	

Purulent discharge occurred during tube treatment in 124 cases (25 %) i.e. 116 ears (41 %) and 79 patients (46 %). When the bacterial culture on tube insertion was positive, discharge occurred in 55 % of the cases, and when Hemophilus influenzae grew in the bacterial culture, discharge occurred in 79 % of the cases. The most common bacteria were Staphylococcus aureus (37.4 %), Diplococcus pneumoniae (12.5 %), Hemophilus influenzae (11.7 %), Staphylococcus albus (8.9 %), Escherichia coli (6.1 %), Streptococcus (5.6 %) and Pseudomonas aeruginosa (5.0 %).

4.1.1.2. Follow up study

Complications of chronic secretory otitis media and tube therapy	22	7.6
Total	290	100.0

In the ears in which chronic secretory otitis media had healed, the appearance of the drum was normal or nearly normal in 130 cases (68.4 %) and abnormal in 60 cases (31.6 %) (Table VII) The appearance of the drum was classified as normal if no abnormality could be observed on examination with Siegle's pneumatic speculum. The pathological drums were divided into subgroups on the basis of their microscopic appearance. The tympanostomy scar was visible

children under 1 year (18 9 %) but that of the 7—8 year olds, i.e those who had just started school was almost as big (14 6 %) The mean age of onset was 4 years 10 months

Adenotomy had been carried out earlier on 48 patients and adenotonsillectomy on 14 In the course of the treatment of chronic secretory otitis media adenotomy was performed on 129 and adenotonsillectomy on 15 patients. 52 of the adenotomies were re-adenotomies No operation was made on 10 patients, 8 of whom had cleft palate, one ozaena and in one patient aged 14 years no adenoid tissue was present.

On admission to hospital 24 children were found to have sinusitis and 4 allergic rhinitis. There was no instance of hypo- or agamma globulinaemia but in 9 children the immunoglobulin values were at the lower limit of normal

An abnormal status of the nasopharynx was seen in 6 patients. In 2 of these the tubal orifices were severely strictured after an earlier adenotomy and in another 2 the orifices were otherwise very narrow One patient after adenotomy had developed a synechia from the soft palate to the roof of the nasopharynx and in another the tori were hypertrophic, practically filling the nasopharynx Very large-sized adenoids were found in 35 children

The mean interval from the diagnosis of secretory otitis media to the insertion of tympanostomy tubes was 8.5 months. In this interval a number of the patients were treated by weekly paracentesis, while others were symptom free for months of even years in the meantime The mean age of the patients at the time of the first insertion of tubes was 5 years 8 months. The tube was inserted only once into 169 ears (58.3 %) twice into 62 ears (21 4 %) three times into 34 ears (11 7 %) and four or more times into 25 ears (8 6 %) The highest number of tympa nostomy tubes per ear was 8 of which 7 were inserted in another hospital All told 511 tubes were inserted to the patients of the present series The mean period during which the tubes remained ventilating was 7 0 months The first tube remained in position for 7 8 months on average the second for 7 2 months the third for 6.3 months and from the fourth onwards for 6 0 months The shortest period was 48 hours, after which the tube was extruded with purulent discharge and the longest 56 months. Tympa notomy had to be carried out twice after the inserted tube had slipped into the tympanum. Both ears healed without complications.

In the preliminary examinations a sample was taken in connection with paracentesis, for bacterial analysis The cultures of these samples were always negative in 74 ears (25.5 %) None of these patients had been treated with antibiotics immediately before paracentesis.

In connection with the insertion of the tympanostomy tube a bacterial sample was taken under operating-microscope control, direct from the paracentesis opening The external meatus was only mechanically cleaned before the procedure. A total of 322 bacterial samples (198 ears) were taken in connection with 511 tube insertions. The bacterial culture of 251 samples (78 %) was negative and that of 71 samples (22 %) positive. The most common bacteria were Hemophilus influenzae Staphylococcus aureus and Staphylococcus albus (Table V)

Table V *Results of bacterial analysis of samples taken in connection with insertion of the tubes*

Organism	No.	% of positive cultures
Hemophilus influenzae	19	26.8
Staphylococcus aureus	14	19 9
Staphylococcus albus	14	19 9
Diplococcus pneumoniae	6	8.4
Klebsiella pneumoniae	4	5 6
Neisseria catarrhalis	4	5.6
Pseudomonas aeruginosa	4	5.6
Aerobacter aerogenes	1	1 4
Alkaligenes faecalis	1	1 4
Escherichia coli	1	1 4
Hafnia	1	1 4
Corynebacterium pseudodifteriae	1	1 4
Candida	1	1 4
Total positive cultures	71	
Negative cultures	251	
Total analyses	322	

4.1.1.3. Case reports of complicated cases

4.1.1.3.1 Dry perforation, 8 patients (8 ears)

1 S.L. 21 years. The patient sought treatment at the age of 14 for impaired hearing. There was no history of otitis, and on admission the hearing level of the right ear was 31 7 dB and of the left 33.3 dB (means of the 500, 1000 and 2000 Hz thresholds). Paracentesis showed mucoid secretion on repeated occasions. Tympanostomy tubes were inserted 3 times into both ears. At the follow-up examination the right-ear tube was in the external meatus, the drum showed a central perforation of 2 mm in diameter and the ear was dry. In the left drum the tube was in position. The hearing level of the right ear was 15.0 dB, of the left 5.0 dB.

2. P.I. 12 years. Impaired hearing was diagnosed at the age of 4 years. Adenotomy was performed but the hearing still remained impaired. At the age of 8, tubes were inserted into both ears. The hearing level prior to tube insertion was on the right 45.0 dB and on the left 13.3 dB. The left ear remained symptom-free after the extrusion of the tube, but in the right the tube had to be re-inserted 5 times. At the follow-up examination a dry central perforation of 2 mm in diameter was noted in the right drum, while the left drum was normal. Both ears had the same hearing level, 3.3 dB.

3. T.A. 7 years. Adenotonsillectomy was performed at the age of 3 for recurrent tonsillitis. At the age of 5 the patient was again brought for treatment, this time for impaired hearing. The hearing level on admission was 18.3 dB in the right and 21.7 dB in the left ear. Tympanostomy tubes were inserted into both ears. There was discharge from the ears and the tubes were extruded. The patient failed to attend the outpatient clinic, and was brought in for treatment one year later for discharge from both ears. The left ear healed with conservative therapy but in the right ear a dry central perforation persisted. At the follow-up examination 6 months later the right ear had a dry perforation of 3 mm in diameter and the left drum showed rigid mobility but paracentesis was negative. The hearing level of the right ear was 18.3 dB and of the left 33.3 dB.

4 S.K 12 years. The patient had undergone adenotonsillectomy at the age of 3. Treatment was required again at the age of 6 for impaired hearing. The hearing level of the right ear was 31 7 dB, of the left 11 7 dB. Tympanostomy tubes were inserted twice into both ears. At the follow-up examination the right drum was normal, but the left drum had a dry central perforation of 2 mm in diameter. The hearing level of the right ear was 15.0 dB of the left 11 7 dB.

5. L.V 3 years. The patient came for treatment at the age of 1 year for recurrent otitis. Paracentesis produced repeatedly glue-like secretion. Tympanostomy tubes were inserted into both ears at the age of 14 months. After the insertion discharge continued for a long time from both ears, and at the age of 18 months ozaena was additionally diagnosed in the patient. Mastoidectomy of both ears was carried out at the age of 20 months for discharge and radiographic mastoiditis. Even then there was discharge from both ears from time to time. At the follow-up examination the tube in the right ear was in position and the ear was dry while a relatively extensive dry central perforation was noted in the left drum. Severe ozaena persisted in the nose.

6. R.V 15 years. The patient had had impaired hearing since the age of 9 He sought treatment at the age of 10 when the hearing level of the right ear was 35.0 dB and of the left 63.3 dB. Tubes were inserted into both ears. The left one was soon extruded, and a perforation along the posterior margin remained in the ear. Later the tube of the right ear was also extruded, and a dry central perforation remained. A modified radical operation was later carried out on the left ear where necrosis of the long process of the incus was found. Reconstruction was effected with a steel wire columella. At the follow-up examination the right drum showed an extensive dry perforation and the left ear a mobile drum. The hearing level of the right ear was 31 7 dB and of the left 16.7 dB.

7 A.O 19 years. Discharge from both ears appeared at the age of 13. A year later the patient sought treatment for impaired hearing. On admission the hearing level of the right ear was 23.3 dB and of the left 18.3 dB. Tympanostomy tubes were inserted into both ears. Both were extruded within six months, and a dry central perforation of 2 mm in diameter remained in the left ear whereas the right drum was normal at the follow-up examination. The hearing level of the right ear was 11.7 dB, of the left 26.7 dB.

8. T K. 11 years. Impaired hearing of both ears was diagnosed at the age of 8. Adenotomy was performed but hearing remained poor Six months later tympanostomy tubes were inserted into both ears. The tubes were extruded within 6 months, and a dry perforation remained in the right ear Since the perforation failed to close within a year and since there was no sign of chronic secretory otitis media, myringoplasty was undertaken. At the follow-up examination one year later both drums were intact, and the hearing level of the right ear was 13.3 dB, of the left 6.7 dB.

Table VII Eardrum appearance in the ears with healed chronic secretory otitis media (changes not mutually excluding)

Eardrum appearance	No	
Tympanosclerotic	29	
Pseudomembranous	22	
Visible tympanostomy scar	15	
Retracted	6	
Atrophic	3	
Adherent to the head of the stapes	3	
Abnormal		60
Normal or nearly normal		130
Total		190

on the cicatricial drums, while in the atrophic either the whole drum or its posterosuperior segment was atrophied.

In 64 ears (22.1 %) the tube was still in position and ventilating and the patients had no symptoms of the disease. In these 64 ears the tympanostomy tube therapy had lasted 24 2 months on average. Purulent discharge from the tympanostomy tube was observed in the follow up study from 5 ears (1 7 %) In 9 ears (3 2 %) chronic secretory otitis media was found to have recurred, while 22 ears (7 6 %) showed complications (Table VIII) The most common was drum perforation in 12 ears. Seven of the perforations were dry and 5 had discharge

Table VIII *Complications of chronic secretory otitis media and tympanostomy tube treatment recorded at the follow-up examination*

Complication	No
Drum perforation dry	7
Drum perforation, with discharge	5
Drum perforation, operated	1
Retracted drum	2
Partly adhesive drum	2
Attic cholesteatoma	2
Tympanic cholesteatoma, operated	2
Necrosis of the long process of incus, operated	1
Total	22

Furthermore, myringoplasty had been performed during the follow up period in one ear of persistent perforation. In the total material therefore the number of perforations following tube therapy was 13 (4.5 %) Two drums (0 7 %) were grossly retracted (para centesis was negative) and 2 drums (0 7 %) partly adhesive to the promontorium One patient had attic cholesteatoma in both ears (0 7 %) although the tympanostomy tubes on both sides were in position and ventilating During the follow up period, a modified radical operation had been performed on 2 ears (0 7 %) for a cholesteatoma of the posterosuperior segment. One ear (0 35 %) had been treated with tympanotomy and the finding was necrosis of the long process of the incus.

Eighteen patients and a total of 35 ears had been treated with tympanostomy tubes for over 2 years The mean period of treatment for these patients was 33 8 months (range 24—60 months) The cleft palate operation had been performed on 3 the orifices of the Eustachian tubes were badly strictured after adenotomy in 2, and one had a severe allergic rhinitis. No causative factor necessitating the extended tube therapy could be demonstrated in 12 patients (23 ears)

During the follow up period, tympanotomy had been made on one ear and it had been found that the stapes was underneath the bifurcate facial nerve and failed to connect with the long process of the incus. No reconstruction was possible.

No differences between age groups 0—5 and 6—14 years were observable in the results of tube therapy 41 9 % of the 76 patients aged 0—5 years at the time of first insertion of the tube, and 43.3 % of the 88 patients who were 6—14 years old at the time of the first insertion, were symptom free after one year Nor could any great differences be observed between the greatest age groups, 0—1 and 7—8 years. Of the former age group 42.8 % and of the latter 47 4 % were symptom free after one year

4.1.1.3. Case reports of complicated cases

4.1.1.3.1. Dry perforation, 8 patients (8 ears)

1. S.L. 21 years. The patient sought treatment at the age of 14 for impaired hearing. There was no history of otitis, and on admission the hearing level of the right ear was 31.7 dB and of the left 33.3 dB (means of the 500, 1000 and 2000 Hz thresholds). Paracentesis showed mucoid secretion on repeated occasions. Tympanostomy tubes were inserted 3 times into both ears. At the follow-up examination the right-ear tube was in the external meatus, the drum showed a central perforation of 2 mm in diameter and the ear was dry. In the left drum the tube was in position. The hearing level of the right ear was 15.0 dB, of the left 5.0 dB.

2. P.J. 12 years. Impaired hearing was diagnosed at the age of 4 years. Adenotomy was performed but the hearing still remained impaired. A the age of 8, tubes were inserted into both ears. The hearing level prior to tube insertion was on the right 45.0 dB and on the left 13.3 dB. The left ear remained symptom-free after the extrusion of the tube, but in the right the tube had to be re-inserted 5 times. At the follow-up examination a dry central perforation of 2 mm in diameter was noted in the right drum, while the left drum was normal. Both ears had the same hearing level, 3.3 dB.

3. T.A. 7 years. Adenotonsillectomy was performed at the age of 3 for recurrent tonsillitis. At the age of 5 the patient was again brought for treatment, this time for impaired hearing. The hearing level on admission was 18.3 dB in the right and 21.7 dB in the left ear. Tympanostomy tubes were inserted into both ears. There was discharge from the ears and the tubes were extruded. The patient failed to attend the outpatient clinic, and was brought in for treatment one year later for discharge from both ears. The left ear healed with conservative therapy but in the right ear a dry central perforation persisted. At the follow-up examination 6 months later the right ear had a dry perforation of 3 mm in diameter and the left drum showed rigid mobility but paracentesis was negative. The hearing level of the right ear was 18.3 dB and of the left 33.3 dB.

4. S.K. 12 years. The patient had undergone adenotonsillectomy at the age of 3. Treatment was required again at the age of 6 for impaired hearing. The hearing level of the right ear was 31.7 dB, of the left 11.7 dB. Tympanostomy tubes were inserted twice into both ears. At the follow-up examination the right drum was normal, but the left drum had a dry central perforation of 2 mm in diameter. The hearing level of the right ear was 15.0 dB, of the left 11.7 dB.

5. L.V. 3 years. The patient came for treatment at the age of 1 year for recurrent otitis. Paracentesis produced repeatedly glue-like secretion. Tympanostomy tubes were inserted into both ears at the age of 14 months. After the insertion discharge continued for a long time from both ears, and at the age of 18 months eczema was additionally diagnosed in the patient. Mastoidectomy of both ears was carried out at the age of 20 months for discharge and radiographic mastoiditis. Even then there was discharge from both ears from time to time. At the follow-up examination the tube in the right ear was in position and the ear was dry while a relatively extensive dry central perforation was noted in the left drum. Severe eczema persisted in the nose.

6. R.V. 15 years. The patient had had impaired hearing since the age of 9. He sought treatment at the age of 10 when the hearing level of the right ear was 35.0 dB and of the left 43.3 dB. Tubes were inserted into both ears. The left one was soon extruded, and a perforation along the posterior margin remained in the ear. Later the tube of the right ear was also extruded, and a dry central perforation remained. A modified radical operation was later carried out on the left ear where necrosis of the long process of the incus was found. Reconstruction was effected with a steel wire columella. At the follow-up examination the right drum showed an extensive dry perforation and the left ear a mobile drum. The hearing level of the right ear was 31.7 dB and of the left 16.7 dB.

7. A.O. 19 years. Discharge from both ears appeared at the age of 13. A year later the patient sought treatment for impaired hearing. On admission the hearing level of the right ear was 23.3 dB and of the left 18.3 dB. Tympanostomy tubes were inserted into both ears. Both were extruded within six months, and a dry central perforation of 2 mm in diameter remained in the left ear whereas the right drum was normal at the follow-up examination. The hearing level of the right ear was 11.7 dB, of the left 26.7 dB.

8. T.K. 11 years. Impaired hearing of both ears was diagnosed at the age of 8. Adenotomy was performed but hearing remained poor. Six months later tympanostomy tubes were inserted into both ears. The tubes were extruded within 6 months, and a dry perforation remained in the right ear. Since the perforation failed to close within a year and since there was no sign of chronic secretory otitis media, myringoplasty was undertaken. At the follow-up examination one year later both drums were intact, and the hearing level of the right ear was 13.3 dB, of the left 6.7 dB.

Table VII *Eardrum appearance in the ears with healed chronic secretory otitis media (changes not mutually excluding)*

Of the former age group 42.8 % and of the latter 47 4 % were symptom free after one year

4.1.1.3. Case reports of complicated cases

4.1.1.3.1. Dry perforation, 8 patients (8 ears)

1. S.L. 21 years. The patient sought treatment at the age of 14 for impaired hearing. There was no history of otitis, and on admission the hearing level of the right ear was 31.7 dB and of the left 33.3 dB (means of the 500, 1000 and 2000 Hz thresholds). Paracentesis showed mucoid secretion on repeated occasions. Tympanostomy tubes were inserted 3 times into both ears. At the follow-up examination the right-ear tube was in the external meatus, the drum showed a central perforation of 2 mm in diameter and the ear was dry. In the left drum the tube was in position. The hearing level of the right ear was 15.0 dB, of the left .0 dB.

2. P.J. 12 years. Impaired hearing was diagnosed at the age of 4 years. Adenotomy was performed but the hearing still remained impaired. At the age of 8, tubes were inserted into both ears. The hearing level prior to the insertion was on the right 45.0 dB and on the left 13.3 dB. The left ear remained symptom-free after the extrusion of the tube, but in the right the tube had to be re-inserted 5 times. At the follow-up examination a dry central perforation of 2 mm in diameter was noted in the right drum, while the left drum was normal. Both ears had the same hearing level, 3.3 dB.

3. T.A. 7 years. Adenotonsillectomy was performed at the age of 3 for recurrent tonsillitis. At the age of 5 the patient was again brought for treatment, this time for impaired hearing. The hearing level on admission was 18.3 dB in the right and 21.7 dB in the left ear. Tympanostomy tubes were inserted into both ears. There was discharge from the ears and the tubes were extruded. The patient failed to attend the outpatient clinic, and was brought in for treatment one year later for discharge from both ears. The left ear healed with conservative therapy but in the right ear a dry central perforation persisted. At the follow-up examination 6 months later the right ear had a dry perforation of 3 mm in diameter and the left drum showed rigid mobility but paracentesis was negative. The hearing level of the right ear was 18.3 dB and of the left 33.3 dB.

4. S.K. 12 years. The patient had undergone adenotonsillectomy at the age of 3. Treatment was required again at the age of 6 for impaired hearing. The hearing level of the right ear was 31.7 dB, of the left 11.7 dB. Tympanostomy tubes were inserted twice into both ears. At the follow-up examination the right drum was normal but the left drum had a dry central perforation of 2 mm in diameter. The hearing level of the right ear was 15.0 dB of the left 11.7 dB.

5. L.V. 3 years. The patient came for treatment at the age of 1 year for recurrent otitis. Paracentesis produced repeatedly glue-like secretion. Tympanostomy tubes were inserted into both ears at the age of 14 months. After the insertion discharge continued for a long time from both ears, and at the age of 18 months ozaena was additionally diagnosed in the patient. Mastoidectomy of both ears was carried out at the age of 20 months for discharge and radiographic mastoiditis. Even then there was discharge from both ears from time to time. At the follow-up examination the tube in the right ear was in position and the ear was dry while relatively extensive dry central perforation was noted in the left drum. Severe ozaena persisted in the nose.

6. R.V. 15 years. The patient had had impaired hearing since the age of 9. He sought treatment at the age of 10 when the hearing level of the right ear was 35.0 dB and of the left 63.3 dB. Tubes were inserted into both ears. The left one was soon extruded, and a perforation along the posterior margin remained in the ear. Later the tube of the right ear was also extruded, and a dry central perforation remained. A modified radical operation was later carried out on the left ear where necrosis of the long process of the incus was found. Reconstruction was effected with steel wire columella. At the follow-up examination the right drum showed an extensive dry perforation and the left ear a mobile drum. The hearing level of the right ear was 31.7 dB and of the left 16.7 dB.

7. A.O. 19 years. Discharge from both ears appeared at the age of 13. A year later the patient sought treatment for impaired hearing. On admission the hearing level of the right ear was 23.3 dB and of the left 18.3 dB. Tympanostomy tubes were inserted into both ears. Both were extruded within six months, and a dry central perforation of 2 mm in diameter remained in the left ear whereas the right drum was normal at the follow-up examination. The hearing level of the right ear was 11.7 dB, of the left 26.7 dB.

8. T.K. 11 years. Impaired hearing of both ears was diagnosed at the age of 8. Adenotomy was performed but hearing remained poor. Six months later tympanostomy tubes were inserted into both ears. The tubes were extruded within 6 months, and a dry perforation remained in the right ear. Since the perforation failed to close within a year and since there was no sign of chronic secretory otitis media, myringoplasty was undertaken. At the follow-up examination one year later both drums were intact, and the hearing level of the right ear was 13.3 dB, of the left 6.7 dB.

4 1 1.3 2. Perforation with discharge, 4 patients (5 ears)

1 T N 14 years. At the age of 9 the hearing was found to be impaired, 15 0 dB in the right ear and 30 0 dB in the left. Adenotomy did not improve hearing and six months later tympanostomy tubes were inserted. The patient neglected treatment of the transient discharge from the ears At the follow up examination the right drum was found to be normal whereas in the left ear there was an extensive central perforation with discharge Bacterial culture showed a growth of E. coli, and radiography disclosed small sclerotic mastoid air cells also in the left ear The hearing level of the right ear was 6 7 dB of the left 36 7 dB

2. R.R. 15 years. The patient s hearing had been impaired since childhood, and adenotonsillectomy had been carried out at the age of 7 Even then the hearing remained impaired but the patient failed to seek treatment. He consulted the otologist next at the age of 11 when the hearing level of the right ear was 25 0 dB and of the left 28.3 dB He again failed to seek treatment, and the hearing remained poor Two years later he was seen again and the hearing level of the right ear was 25 0 dB of the left 21 7 dB. Tympanostomy tubes were then inserted into both ears. There was discharge from both ears and the tubes had to be re-inserted one year later Even then the discharge continued from both ears, but was not treated and the tubes were extruded At the follow-up examination 3 months later the right drum was normal the left ear showed a small moist central perforation on bacterial culture grew Klebsiella pneumoniae, and a number of sclerotic mastoid air cells were seen in the radiogram. The hearing level of the right ear was 1 7 dB of the left 31 7 dB

3. M.T 5 years. The patient was a mongoloid severely mentally retarded Tympanostomy tubes were inserted into both ears at the age of 4 years for chronic secretory otitis media. The tubes were extruded relatively soon after the operation and purulent discharge occurred. At the follow up examination a year later small central perforations with discharge were noted in both ears. Pseudomonas aeruginosa grew in both ears on bacterial culture.

4 O N 11 years. Adenotonsillectomy was carried out at the age of 5 One year later the patient was seen for impaired hearing Tympanostomy tubes were inserted into both ears. After extrusion of the tubes the ears remained symptom-free for 2 years, after which the left ear showed discharge. At the follow up examination the right drum was found to be normal, the left showed a small central perforation with discharge. Staphylococcus aureus grew on bacterial culture.

4 1 1.3 3 Attic cholesteatoma, 1 patient (2 ears)

1 H H 11 years. Impaired hearing was discovered at the age of 7 when adenotomy was carried out. Even after this the hearing remained impaired, and tonsillectomy was carried out at the age of 8. The hearing was still impaired in the right ear it was 15.0 dB and in the left 30 0 dB. Tubes were inserted into both ears. Extrusion of both tubes occurred 7 months later and the ears remained symptom free for 5 months, after which the disease recurred and both ears had to be re-fitted with tubes. Six months later the left-ear tube was extruded and a new one was re-inserted Purulent discharge from the left ear persisted for about a fortnight. One year later tubes again had to be re-inserted into both ears. On this occasion, an attic cholesteatoma was diagnosed in both ears and its removal through the external meatus was not entirely successful At the follow-up examination cholesteatomas were diagnosed in both attic regions. The hearing level of the right ear was 10.0 dB and of the left similarly 10 0 dB The tubes were in position in both ears.

An atticoantrotomy of the left ear was carried out after the follow-up examination. It revealed a cholesteatoma approximately the size of a pea, situated partly under and partly on top of the ossicular chain Reconstruction of the auditory ossicles was effected by placing the incus onto the head of the stapes. After the operation the hearing level of the left ear was 35 0 dB

4 1 1 3 4 Cholesteatoma of the posterosuperior segment 2 patients (2 ears)

1 M M 16 years. The patient had had ear trouble ever since the age of 10 He was first seen at the age of 12 when adenotomy was carried out and a tympanostomy tube inserted into the left ear Preoperatively the hearing level of the left ear was 68.3 dB. The tube was extruded within a few months. A marginal perforation and a cholesteatoma were seen in the region of the posterosuperior segment of the drum (the cholesteatoma had apparently been there even before the insertion of the tube) A modified radical operation was made 6 months later and a cholesteatoma entering the antrum was seen. At the follow-up examination the right ear was found to have a normal drum while that

of the left ear showed reduced mobility The hearing level of the right ear as 3.3 dB and of the left 36.7 dB.

2. R.V 15 years. Impaired hearing was discovered at the age of 9 The patient was first seen at the age of 10. The right ear was found to have a drum of reduced mobility and the left ear one that was practically adhesive. The hearing level of the right ear was 35.0 dB and of the left 63.3 dB. Tympanostomy tubes were inserted into both. Discharge from the left ear was noted. A perforation along the posterior margin remained in the drum. T years later a cholesteatoma was found, extending to the antrum, and there was necrosis of the long process of the incus. Reconstruction of the auditory ossicles was effected with steel wire columella. At the follow-up examination the right drum showed a dry perforation hile the left drum as intact and mobile. The hearing level of the right ear was 31 7 dB and of the left, 16.7 dB.

4 1.1.3.5. Conductive hearing defect, 1 patient, (2 ears)

1. S.T 9 years. The patient was first examined for impaired hearing at the age of 5. Even after an adenotomy the hearing remained impaired, although the movement of the drums was moderately good, and only little fluid was aspirated by paracentesis. Tympanostomy tubes were inserted into both ears one year later Paracentesis as now bilaterally negative. Within less than a year the tubes were extruded, and the drums of both ears showed good mobility At the follow-up examination both drums showed normal mobility The hearing level of the right ear was 35.0 dB, of the left 31 7 dB. The bone conduction hearing of both ears was on the zero level. This defect was suspected to depend on bilateral tympanal anomaly but no ultimate cause can be verified until tympanotomy is carried out

4 1 2. *Patients treated without tympanostomy*

The group comprised 17 children with chronic secretory otitis media. In 16 the disease was bilateral and in one unilateral. The material therefore consisted of 33 ears. There were 10 boys (59 %) and 7 girls (41 %)

4 1.2.1 Preoperative history and data from the time of treatment

The chronic secretory otitis media of the patients of this group was treated with repeated paracentesis and adenotomy or adenotonsillectomy but the treatment was not completed since 13 patients failed to attend the outpatient clinic and the attendance of 4 patients was no longer considered necessary after a symptom-free period (c. 1 month) which, in retrospect, seems too short.

The patients had earlier been healthy Only 3 had had recurrent tonsillitis, while 8 children had had episodes of acute otitis media, and 4 had had discharge from the ear Five children had no previous history of otitis media.

The onset of the symptoms of secretory otitis media had occurred at the mean age of 7 years 4 months (range 6 months to 9 years)

Adenotomy had previously been carried out on 6 children. During the course of treatment, 8 children underwent adenotomy and 9 adenotonsillectomy (including some that had earlier undergone adenotomy) On admission 3 children had sinusitis, one allergic rhinitis and 2 had adenoids obstructing the nasopharynx.

The duration of treatment, on average, was 6.1 months (range 1 month to 22 months) during which time the patients were treated if required with paracentesis and courses of antibiotics. At the last visit to the outpatient clinic the appearance and mobility of the drum were normal in 7 ears, whereas in 7 ears the drum had reduced mobility and paracentesis produced a glue-like effusion. In connection with paracentesis, 50 samples (30 ears) were taken for bacterial culture. The culture was negative on 37 samples (74 %) and positive on 13 (26 %) The verified bacteria were Staphylococcus albus (46.2 %) Staphylococcus aureus (23 1 %) Streptococcus (23 1 %) and Hemophilus influenzae (7 6 %)

4 1 1.3 2. Perforation with discharge 4 patients (5 ears)

1 T.N 14 years. At the age of 9 the hearing was found to be impaired 15 0 dB in the right ear and 30.0 dB in the left Adenotomy did not improve hearing and six months later tympanostomy tubes were inserted. The patient neglected treatment of the transient discharge from the ears. At the follow-up examination the right drum was found to be normal whereas in the left ear there was an extensive central perforation with discharge. Bacterial culture showed a growth of E coli, and radiography disclosed small sclerotic mastoid air cells also in the left ear The hearing level of the right ear was 6.7 dB of the left 36 7 dB

2. R.R. 15 years. The patient s hearing had been impaired since childhood and adenotonsillectomy had been carried out at the age of 7 Even then the hearing remained impaired but the patient failed to seek treatment He consulted the otologist next at the age of 11 when the hearing level of the right ear was 25 0 dB, and of the left 28.3 dB He again failed to seek treatment, and the hearing remained poor Two years later he was seen again and the hearing level of the right ear was 25 0 dB of the left 21 7 dB. Tympanostomy tubes were then inserted into both ears. There was discharge from both ears and the tubes had to be re inserted one year later Even then the discharge continued from both ears, but was not treated and the tubes were extruded. At the follow-up examination 3 months later the right drum was normal the left ear showed a small, moist central perforation on bacterial culture grew Klebsiella pneumoniae and a number of sclerotic mastoid air cells were seen in the radiogram. The hearing level of the right ear was 1 7 dB of the left 31 7 dB

3. M T 5 years. The patient was a mongoloid, severely mentally retarded Tympanostomy tubes were inserted into both ears at the age of 4 years for chronic secretory otitis media The tubes were extruded relatively soon after the operation and purulent discharge occurred. At the follow up examination a year later small central perforations with discharge were noted in both ears. Pseudomonas aeruginosa grew in both ears on bacterial culture.

4 Q N 11 years. Adenotonsillectomy was carried out at the age of 5 One year later the patient was seen for impaired hearing Tympanostomy tubes were inserted into both ears. After extrusion of the tubes the ears remained symptom-free for 2 years, after which the left ear showed discharge. At the follow up examination the right drum was found to be normal, the left showed a small central perforation with discharge. Staphylococcus aureus grew on bacterial culture.

4 1 1.3 3 Attic cholesteatoma 1 patient (2 ears)

1 H H 11 years. Impaired hearing was discovered at the age of 7 when adenotomy was carried out. Even after this the hearing remained impaired, and tonsillectomy was carried out at the age of 8. The hearing was still impaired In the right ear it was 15.0 dB and in the left 30 0 dB. Tubes were inserted into both ears. Extrusion of both tubes occurred 7 months later and the ears remained symptom free for : months after which the disease recurred and both ears had to be re-fitted with tubes. Six months later the left-ear tube was extruded and a new one was re-inserted. Purulent discharge from the left ear persisted for about a fortnight. One year later tubes again had to be re-inserted into both ears. On this occasion an attic cholesteatoma was diagnosed in both ears and its removal through the external meatus was not entirely successful At the follow-up examination cholesteatomas were diagnosed in both attic regions. The hearing level of the right ear was 10 0 dB, and of the left similarly 10.0 dB. The tubes were in position in both ears.

An atticoantrotomy of the left ear was carried out after the follow up examination. It revealed a cholesteatoma approximately the size of a pea, situated partly under and partly on top of the ossicular chain Reconstruction of the auditory ossicles was effected by placing the incus onto the head of the stapes. After the operation the hearing level of the left ear was 35 0 dB

4 1 1.3 4 Cholesteatoma of the posterosuperior segment 2 patients (2 ears)

1 M M. 16 years. The patient had had ear trouble ever since the age of 10 He was first seen at the age of 12 when adenotomy was carried out and a tympanostomy tube inserted into the left ear Preoperatively the hearing level of the left ear was 68.3 dB. The tube was extruded within a few months. A marginal perforation and a cholesteatoma were seen in the region of the posterosuperior segment of the drum (the cholesteatoma had apparently been there even before the insertion of the tube) A modified radical operation was made 6 months later and a cholesteatoma entering the antrum was seen. At the follow-up examination the right ear was found to have a normal drum while that

4.2. HEARING RESULTS

4.2.1. Total material

The hearing results presented under this heading cover all the patients of the present material whose hearing could be reliably measured.

Table X. Hearing level in 95 patients with chronic secretory otitis media on admission. The air conduction figures are mean values for 161 ears, bone conduction figures those for 122 ears

Frequency	Hearing level (dB)			
	Air conduction		Bone conduction	
(Hz)	Mean	S.D	Mean	S.D
125	28.7	11.4		
250	27.4	12.4	4.6	5.2
500	29.6	12.7	4.0	6.0
1000	30.1	13.8	3.2	7.5
2000	23.0	12.0	1.7	7.4
4000	28.8	14.5	3.4	8.6
6000	31.9	14.9		
8000	33.8	14.6		

On admission the hearing level could be measured in 95 patients with chronic secretory otitis media, representing 161 ears. The mean values and standard deviations of the air and bone conduction thresholds at different frequencies are presented in Table X. The mean air conduction threshold of the speech frequencies of the total material (mean value of the thresholds of 500 1000 and 2000 Hz) was 27.6 dB (S.D 12.8) the corresponding mean bone conduction threshold 3.0 dB (S.D 7.1) and the mean air-bone gap 24.6 dB. The youngest of the patients examined with audiometry was 4 years, and the mean age was 6.6 years. The mean air conduction threshold at 2000 Hz of the total material was statistically significantly better ($p < 0.01$) than the mean air conduction threshold at 250 Hz and highly significantly ($p < 0.001$) better than at the other frequencies. Statistically significant differences could not be recorded in the bone conduction thresholds.

Table XI. Hearing level in 146 patients with chronic secretory otitis media at the follow-up examination. The air conduction figures are mean values for 238 ears, bone conduction figures those for 40 ears.

Frequency	Hearing level (dB)			
	Air conduction		Bone conduction	
(Hz)	Mean	S.D	Mean	S.D
125	17.4	10.8		
250	15.1	10.7	7.1	5.3
500	14.0	11.5	5.5	4.5
1000	12.9	11.8	5.5	7.5
2000	10.0	11.1	3.9	9.2
4000	14.2	12.3	7.4	8.0
6000	19.2	13.9		
8000	20.7	15.1		

At the follow-up examination, on average 3 years 2 months later the hearing examination could be reliably carried out on 146 patients, and a total of 238 ears. The mean values and standard deviations of the air and bone conduction thresholds at different frequencies are presented in Table XI. The mean air conduction threshold at speech frequencies was 12.3 dB (S.D 11.5) the corresponding mean bone conduction value

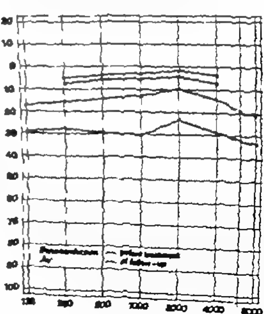

Fig. 2. The mean audiogram of the total material before treatment (161 ears) and at follow-up (238 ears).

4.1.2.2. Follow up study

The follow up examination was attended by 15 patients who had had chronic secretory otitis media in a total of 29 ears Two patients both with bilateral disease, failed to attend One of them wrote a letter stating that he had had no ear trouble since his last visit to the outpatient clinic and that his hearing acuity had been found normal at the audiometric examination at school The data concerning this patient were taken from the record of his last visit to the outpatient clinic when the drum status had been normal and the hearing level good in both ears, and the patient had been symptom-free for a year

The mean follow up period was 4 years 7 months (range 3 years 3 months to 7 years 3 months)

Table IX *Eardrum appearance at the follow up examination of the ears treated without tympanostomy*

Eardrum appearance	No
Retracted	2
Atrophic	2
Tympanosclerotic	1
Pseudomembranous	1
Totally adhesive	2
Abnormal, total	8
Normal or nearly normal	23
Total	31

In no ear was chronic secretory otitis media found at the follow up examination. The drum appearance was normal or nearly normal in 23 ears (74 2 %) and abnormal in 8 ears (25 8 %) (Table IX) In 2 ears (6.5 %) the drum was retracted and in another 2 (6.5 %) atrophic. Tympanosclerosis was diagnosed in 1 drum (3 2 %) and 1 drum (3 2 %) was pseudomembranous In one patient both drums (6.5 %) were totally adhesive except at the tubal orifice where there was bilaterally a small air-containing area. The treatment of this patient had been irregular ever since the beginning and the patient had failed to attend the outpatient clinic.

The mobility of the drum at the follow-up examination was normal or nearly normal in 27 ears (87 %) reduced in 2 ears (6.5 %) (paracentesis negative in both) and in the 2 ears mentioned above (6.5 %) the drum was adhesive.

4.1.2.3 Case reports of complicated cases

4.1.2.3.1 Drum of reduced mobility 1 patient (2 ears)

1 S K 15 years. Since the age of 7 the bearing of both ears had been impaired. The patient was first seen at the age of 8 when both drums showed reduced mobility and paracentesis produced a glue-like effusion On admission the hearing level of the right ear was 33.3 dB and of the left ear 30 0 dB. Adenotomy was carried out 2 months later Following this the patient failed to attend the outpatient clinic. At a follow up examination 3 years later both drums were found to be thickened and of greatly reduced mobility Paracentesis was bilaterally negative. The hearing level of the right ear was 30 0 dB and of the left ear 13.3 dB.

4.1.2.3.2 Adhesive drum, 1 patient (2 ears)

1 K.R. 14 years. At the age of 10 the patient had had discharge from both ears, and the hearing had subsequently been impaired. The patient was first seen one year later and at that time the right drum had a small perforation with discharge while the left drum showed reduced mobility The hearing level of the right ear was 38.3 dB and of the left ear 35 0 dB. After adenotomy had been performed, the left ear was symptom-free but transient purulent discharge occurred from the right ear Some 6 months after the adenotomy both drums showed reduced mobility and paracentesis yielded a glue-like effusion. The hearing level of the right ear was now 31 7 dB and of the left ear 30 0 dB After this the patient failed to visit the outpatient clinic, and there was discharge from the ears which was left untreated At the follow-up examination the drums were found to be adhesive except at the tubal orifice where both ears showed a small air-containing area. Radiography disclosed mastoid air cells that were almost completely sclerosed The hearing level of the right ear was 51 7 dB and of the left ear similarly 51 7 dB.

4.2. HEARING RESULTS

4.2.1 Total material

The hearing results presented under this heading cover all the patients of the present material whose hearing could be reliably measured.

Table X. Hearing level in 95 patients with chronic secretory otitis media on admission. The air conduction figures are mean values for 161 ears, bone conduction figures those for 122 ears

Frequency	Hearing level (dB)			
	Air conduction		Bone conduction	
(Hz)	Mean	S.D	Mean	S.D
125	28.7	11.4		
250	27.4	12.4	4.6	5.2
500	29.6	12.7	4.0	6.0
1000	30.1	13.8	3.2	7.5
2000	23.0	12.0	1.7	7.4
4000	28.8	14.5	3.4	8.6
6000	31.9	14.9		
8000	33.8	14.6		

On admission, the hearing level could be measured in 95 patients with chronic secretory otitis media, representing 161 ears. The mean values and standard deviations of the air and bone conduction thresholds at different frequencies are presented in Table X. The mean air conduction threshold of the speech frequencies of the total material (mean value of the thresholds of 500, 1000 and 2000 Hz) was 27.6 dB, (S.D 12.8) the corresponding mean bone conduction threshold 3.0 dB (S.D 7.1) and the mean air-bone gap 24.6 dB. The youngest of the patients examined with audiometry was 4 years, and the mean age was 8.6 years. The mean air conduction threshold at 2000 Hz of the total material was statistically significantly better ($p<0.01$) than the mean air conduction threshold at 250 Hz and highly significantly ($p<0.001$) better than at the other frequencies. Statistically significant differences could not be recorded in the bone conduction thresholds.

Table XI. Hearing level in 146 patients with chronic secretory otitis media at the follow-up examination. The air conduction figures are mean values for 238 ears, bone conduction figures those for 40 ears.

Frequency	Hearing level (dB)			
	Air conduction		Bone conduction	
(Hz)	Mean	S.D	Mean	S.D
125	17.4	10.8		
250	15.2	10.7	7.1	5.3
500	14.0	11.5	5.5	4.5
1000	12.9	11.8	5.5	7.5
2000	10.0	11.1	3.9	9.2
4000	14.2	12.3	7.4	8.0
6000	19.2	13.9		
8000	20.7	15.1		

At the follow-up examination, on average 3 years 2 months later the hearing examination could be reliably carried out on 146 patients, and a total of 238 ears. The mean values and standard deviations of the air and bone conduction thresholds at different frequencies are presented in Table XI. The mean air conduction threshold at speech frequencies was 12.3 dB (S.D 11.5) the corresponding mean bone conduction value

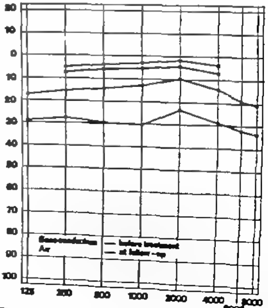

Fig. 2. The mean audiogram of the total material before treatment (161 ears) and at follow-up (238 ears)

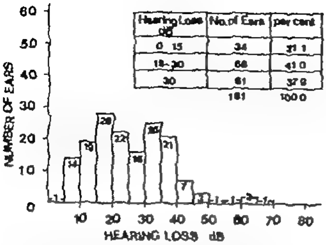

Fig. 3. Air conduction threshold at speech frequencies (average of the frequencies 500, 1000 and 2000 Hz) in the total material on admission for treatment.

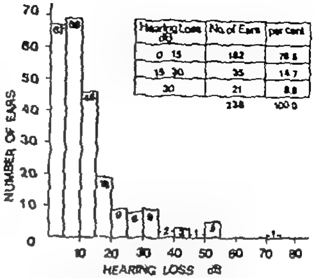

Fig. 4. Air conduction threshold at speech frequencies (average of the frequencies 500, 1000 and 2000 Hz) in the total material at follow up.

5.0 dB (S.D. 7.2) and the mean air bone gap 7.3 dB. Compared with the pre-treatment values the air conduction threshold had improved by 15.3 dB (the difference was statistically highly significant, $p<0.001$), the bone conduction threshold had deteriorated by 2.0 dB (the difference was not statistically significant) and the mean air bone gap had diminished by 17.3 dB (Fig. 2). The youngest patient undergoing audiometric examination at the follow up study was 3 years and the mean age was 9.8 years.

When first seen the air conduction threshold at speech frequencies exceeded 30 dB in 61 ears (37.9 %) (Fig. 3). At the follow up examination the air conduction threshold at speech frequencies exceeded 30 dB in 21 ears (8.8 %) (Fig. 4).

At the follow up examination 4 patients were found to have an air conduction threshold exceeding 30 dB at speech frequencies in both ears. Two of these patients had a perceptive hearing defect exceeding 30 dB in both ears, one had an unexplicable conductive hearing defect in both ears and the fourth had a bilateral adhesive otitis media resulting from neglected therapy.

The correlation of the final hearing result with the distance from hospital is presented in Table XII. The patients who lived at a distance of less than 100 km from the hospital had at the follow up examination an air conduction threshold that at speech frequencies was better by 2.8 dB than those living at a distance exceeding 100 km (the difference was not statistically significant) while the air conduction threshold at speech frequencies on admission had been practically the same in both groups.

In 2 ears the bone conduction threshold at the follow up examination was found to have

Table XII. *Influence of distance from hospital on the hearing result. The mean air conduction threshold at speech frequencies (average of the frequencies 500, 1000 and 2000 Hz) on admission for treatment and at follow-up in patients living at a distance of less than 100 km from hospital, compared with the corresponding values for those living at a distance of over 100 km from hospital.*

Distance	Threshold on admission (dB)	No. of ears	Threshold at follow-up (dB)	No. of ears	Improvement in threshold (dB)
under 100 km	27.2	67	10.8	116	16.4
over 100 km	27.9	94	13.6	122	14.3

deteriorated during treatment. In one of these ears, mastoidectomy had been carried out for prolonged discharge and radiographic mastoiditis. At the follow-up examination the bone conduction threshold was found to have fallen to the 20 dB level at 4000 Hz. In addition a 70 dB high-tone loss at 6000 and 8000 Hz was observed in the air conduction thresholds. In the other of these ears, tympanotomy had been made and an anomalous middle ear been diagnosed, but no reconstruction could be carried out. At the follow-up examination, the bone conduction threshold was found to be at the 20 dB level at all frequencies, while air conduction threshold was at the 70—80 dB level.

4.2.2 The tympanostomy group

4.2.2.1 Total group

Of all patients treated with tympanostomy the hearing of 82 patients, a total of 134 ears, could be measured by audiometry on admission. Ears in which a tympanal anomaly had been diagnosed or was suspected, ears with a perceptive hearing defect and ears that had been operated on during the follow-up period were excluded from the statistical treatment. The mean values and standard deviations of the air and bone conduction thresholds of the different frequencies are presented in Table XIII The

Table XIII *Hearing level on admission of 82 patients treated with tympanostomy The air conduction figures are mean values for 134 ears, bone conduction figures for 102 ears.*

Frequency (Hz)	Hearing level (dB) Air conduction Mean	S.D	Bone conduction Mean	S.D

5 0 dB (S D 7 2) and the mean air-bone gap 7.3 dB Compared with the *pre-treatment values* the air conduction threshold had improved by 15 3 dB (the *difference was statistically highly* significant $p<0\ 001$) the bone conduction threshold had deteriorated by 2.0 dB (the difference was not statistically significant) and the mean air bone gap had diminished by 17.3 dB (Fig 2) The youngest patient undergoing audiometric examination at the follow up study was 3 years and the mean age was 9 8 years

When first seen the air conduction threshold at speech frequencies exceeded 30 dB in 61 ears (37 9 %) (Fig 3) At the follow up examination the air conduction threshold at speech frequen cies exceeded 30 dB in 21 ears (8.8 %) (Fig 4)

At the follow up examination 4 patients were found to have an air conduction threshold exceeding 30 dB at speech frequencies in both ears. Two of these patients had a perceptive hearing defect exceeding 30 dB in both ears one had an unexplicable conductive hearing defect in both ears, and the fourth had a bilateral adhesive otitis media resulting from neglected therapy

The correlation of the final hearing result with the distance from hospital is presented in Table XII The patients who lived at a *distance* of less than 100 km from the hospital had at the follow up examination an air conduction threshold that at speech frequencies was better by 2 8 dB than those living at a distance exceeding 100 km (the difference was not statistically significant) while the air conduction threshold at speech frequencies on admission had been practically the same in both groups.

In 2 ears the bone conduction threshold at the follow up examination was found to have

Table XII *Influence of distance from hospital on the hearing result. The mean air conduction threshold at speech frequencies (average of the frequencies 500 1000 and 2000 Hz) on admission for treatment and at follow-up in patients living at a distance of less than 100 km from hospital, compared with the corresponding values for those living at a distance of over 100 km from hospital.*

Distance	Threshold on admission (dB)	No. of ears	Threshold at follow up (dB)	No. of ears	Improvement in threshold (dB)
under 100 km	27.2	67	10 8	116	16.4
over 100 km	27 9	94	13.6	122	14.3

deteriorated during treatment. In one of these ears, mastoidectomy had been carried out for prolonged discharge and radiographic mastoiditis. At the follow-up examination the bone conduction threshold was found to have fallen to the 20 dB level at 4000 Hz. In addition, a 70 dB high-tone loss at 6000 and 8000 Hz was observed in the air conduction thresholds. In the other of these ears, tympanotomy had been made and an anomalous middle ear been diagnosed, but no reconstruction could be carried out. At the follow-up examination, the bone conduction threshold was found to be at the 20 dB level at all frequencies, while air conduction threshold was at the 70—80 dB level.

2.2. *The tympanotomy group*

2.2.1 T o t a l g r o u p

Of all patients treated with tympanotomy the hearing of 82 patients, a total of 134 ears, could be measured by audiometry on admission. Ears in which a tympanal anomaly had been diagnosed or was suspected, ears with a perceptive hearing defect and ears that had been operated on during the follow up period were excluded from the statistical treatment. The mean values and standard deviations of the air and bone conduction thresholds of the different frequencies are presented in Table XIII. The mean air conduction threshold at speech frequencies was 27.1 dB (S.D. 12.5) the corresponding mean bone conduction threshold 2.6 dB (S.D. 5.5) and the mean air bone gap 24.5 dB. The youngest patient examined with audiometry was 4 years old, the mean age was 8.6 years.

Table XIII. *Hearing level on admission of 82 patients treated with tympanotomy. The air conduction figures are mean values for 134 ears, bone conduction figures for 102 ears.*

Frequency	Hearing level (dB)

8000	16.8	12.8		

An audiometric hearing test had been carried out on average 1 month after the tube insertion on 94 patients representing 147 ears (Table XIV). The mean air conduction threshold of the speech frequencies was 9.5 dB (S.D. 8.8) the corresponding bone conduction threshold 1.7 dB (S.D. 6.0) and the mean air-bone gap 7.8 dB. The youngest patient tested with audiometry was 4 years old, and the mean age was 8.7 years. Compared with the preoperative values, the air conduction threshold had improved by 17.6 dB (the difference was statistically highly significant, $p < 0.001$) the bone conduction threshold by 0.9 dB (the difference was not statistically significant) and the air-bone gap had diminished by 16.7 dB.

In connection with the follow-up examination on average 2 years 8 months after the insertion of the tube a hearing test was carried out on 124 patients representing 202 ears (Table XV). The mean air conduction threshold at speech frequencies was 11.3 dB (S.D. 9.2) the corresponding mean bone conduction value 3.2 dB (S.D. 3.9) and the mean air bone gap 8.1

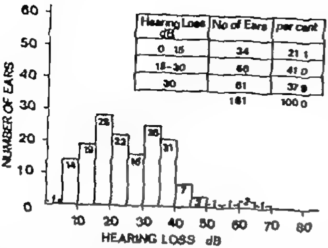

Fig 3 Air conduction threshold at speech frequencies (average of the *frequencies 500 1000* and *2000 Hz)* in the total material on admission for treatment.

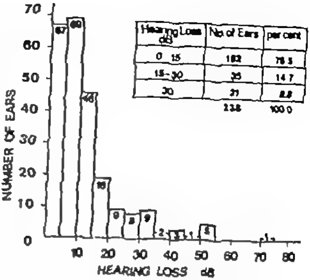

Fig 4 Air conduction threshold at speech frequencies (*average of the frequencies 500 1000* and *2000 Hz)* in the total material at follow-up

5 0 dB (S D 7 2) and the mean air bone gap 7.3 dB Compared with the pre-treatment values the air conduction threshold had improved by 15 3 dB (the difference was statistically highly significant $p < 0\ 001$) the bone conduction threshold had deteriorated by 2.0 dB (the difference was not statistically significant) and the mean air bone gap had diminished by 17 3 dB (Fig 2) The youngest patient undergoing audiometric examination at the follow up study was 3 years and the mean age was 9 8 years

When first seen the air conduction threshold at speech frequencies *exceeded 30 dB* in 61 ears (37 9 %) (Fig 3) *At the follow up examination* the air conduction threshold at speech frequencies exceeded 30 dB in 21 ears (8 8 %) (Fig 4)

At the follow up examination 4 patients were found to have an air conduction threshold exceeding 30 dB at speech frequencies in both ears. Two of these patients had a perceptive hearing defect exceeding 30 dB in both ears one had an unexplicable conductive hearing defect in both ears, *and the fourth had* a bilateral adhesive otitis media resulting from neglected therapy

The correlation of the final hearing result with the distance from hospital is presented in Table XII The patients who lived at a distance *of* less than 100 km from the hospital had at the follow up examination an air conduction threshold that at speech frequencies was better by 2.8 dB than those living at a distance exceeding 100 km (the difference was not *statistically significant)* while the air conduction *threshold at speech frequencies* on admission had been practically the same in both groups.

In 2 ears the bone conduction threshold at the follow up examination was found to have

Table XII *Influence of distance from hospital on the hearing result. The mean air conduction threshold at speech frequencies (average of the frequencies 500, 1000 and 2000 Hz) on admission for treatment and at follow-up in patients living at a distance of less than 100 km from hospital, compared with the corresponding values for those living at a distance of over 100 km from hospital.*

Distance	Threshold on admission (dB)	No. of ears	Threshold at follow-up (dB)	No. of ears	Improvement in threshold (dB)
under 100 km	27 2	67	10 8	116	16.4
over 100 km	27 9	94	13.6	122	14.3

Table XVII. *Hearing level 1 month after tube insertion in 64 patients treated with tympanostomy whose disease had healed by the time of the follow-up. The air conduction figures are mean values for 94 ears, bone conduction figures for 4 ears.*

conduction threshold had deteriorated by 0 5 dB from the preoperative value (the difference was not statistically significant) and by 1.5 dB from the immediate postoperative value (the difference was not statistically significant) The air bone gap had diminished by 16 4 dB from the preoperative value but increased by 0.3 dB from the postoperative value.

4.2.2 2. Chronic secretory otitis media healed at the follow up examination

This group comprises the patients in whom chronic secretory otitis media was found to have healed during the follow up period, the tubes had been extruded and the eardrums were intact.

On admission, the audiometric test could be carried out on 56 patients, and a total of 88 ears (Table XVI) The mean air conduction threshold at speech frequencies was 25 8 dB (S D 12.1) the corresponding mean bone conduction threshold was 2 0 dB (S D 5 9) and the mean air bone gap 23 8 dB The youngest of the patients tested was 4 years old, and the mean age was 9 2 years

About 1 month after the insertion of the tubes the hearing of 64 patients, representing 94 ears, had been tested (Table XVII) The mean air

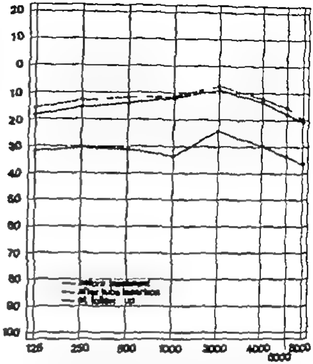

Fig 9 Mean audiogram (air conduction) of ears *treated with tympanostomy tubes and with tubes in* position at follow-up on admission (28 ears) 1 month after tube insertion (34 ears) and at follow-up (29 ears)

conduction threshold had deteriorated by 0 6 dB from the preoperative value (the difference was *not* statistically significant) The mean air bone gap had *diminished* by 16 8 dB from the preoperative value

On admission for treatment the air conduc tion threshold at speech frequencies exceeded 30 dB on 35 ears (39 8 %) (Fig 7) but at the follow up examination in only one (0 7 %) (Fig 6)

4 2.2.3 Tubes in position at the follow up examination

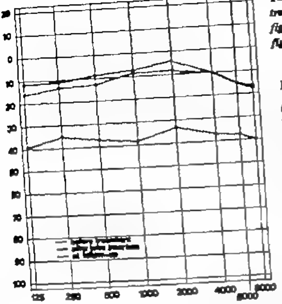
On admission the hearing of 15 patients and a total of 28 ears had been tested The mean air conduction threshold at speech frequencies in the whole group was *29 6 dB (S D 12.4) the corresponding mean bone conduction threshold* 3 2 dB (S D 4 6) and the mean air bone gap 26 4 dB The youngest of the patients tested was 4 years old, and the mean age was 7 1 years

About 1 month after the insertion of the tubes a hearing test was made on 19 patients representing 34 ears. The mean air conduction threshold at speech frequencies was *10 0 dB (S D 7 2) it had improved* by 19 6 dB from the preoperative value (the difference was statisti cally highly significant p <0 001) The youngest of the patients tested was 4 years old and the mean age was 7 3 years.

At the follow up examination the audiometric hearing test was carried out on 16 patients and a total of 29 ears. The mean air *conduction threshold at speech frequencies was 11.5 dB (S D 9 7)* The improvement from the preoperative value was 18.1 dB (the difference was statistically highly significant p <0 001) and deterioration from the immediate postoperative value was 1.5 dB (the difference was not statistically significant) (Fig 9) The youngest of the patients tested was 3 *years old, and the mean* age was 9 2 years.

4 2.2.4 The cleft palate pa tients

The tympanostomy group contained *10 operated cleft palate patients. On admission the hearing of* 3 patients and a total of 6 ears had been tested The mean air conduction threshold at speech frequencies was 36 1 dB (S D 9 2) the corresponding bone conduction threshold 2.9 dB (S D 3 3) and the mean air-bone gap 33.2 dB



[Fi]g. 10. Mean audiogram (air conduction) of the cleft [p]alate patients treated with tympanostomy tubes, on [a]dmission (6 ears) 1 month after tube insertion (6 [e]ars) and at follow-up (10 ears)

The youngest patient tested was 7 years old, and the mean age was 7 7 years.

At the follow-up examination the audiometric hearing test was carried out on 5 patients representing 10 ears. Three patients (6 ears) still had the tubes in position. The mean air conduction threshold at speech frequencies was 6.7 dB (S.D 5.2). Compared with the preoperative value the mean air conduction threshold had improved by 29 4 dB (the difference was statistically highly significant, $p<0.001$) (Fig. 10). The youngest of the patients tested was 4 years old and the mean age was 9 2 years.

4.2.3. Patients treated without tympanostomy

On admission, the hearing of 10 patients representing 18 ears could be measured by audiometry (Table XIX). The mean air conduction threshold at speech frequencies was 22.8 dB (S.D 12.1) the corresponding bone conduction threshold −2.0 dB (S.D 4.2) and

conduction threshold had deteriorated by 0 6 dB from the preoperative value (the difference was not statistically significant) The mean air bone gap had diminished by 16 8 dB from the preoperative value

On admission for treatment the air conduction threshold at speech frequencies exceeded 30 dB on 35 ears (39 8 %) (Fig 7) but at the follow up examination in only one (0 7 %) (Fig 8)

4.2.2.3 Tubes in position at the follow up examination

On admission the hearing of 15 patients, and a total of 28 ears had been tested The mean air conduction threshold at speech frequencies in the whole group was 29 6 dB (S D 12 4) the corresponding mean bone conduction threshold 3 2 dB (S D 4 6) and the mean air bone gap 26 4 dB The youngest of the patients tested was 4 years old and the mean age was 7 1 years.

About 1 month after the insertion of the tubes a hearing test was made on 19 patients representing 34 ears. The mean air conduction threshold at speech frequencies was 10 0 dB (S D 7 2) it had improved by 19 6 dB from the preoperative value (the difference was statistically highly significant, $p < 0\ 001$) The youngest of the patients tested was 4 years old and the mean age was 7 3 years

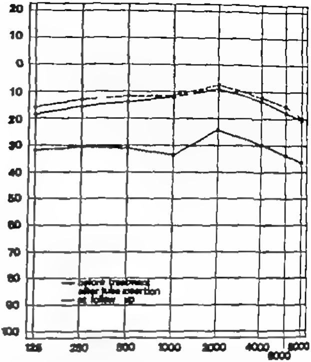

Fig 9 Mean audiogram (air conduction) of ears treated with tympanostomy tubes and with tubes in position at follow up on admission (28 ears) 1 month after tube insertion (34 ears) and at follow-up (29 ears)

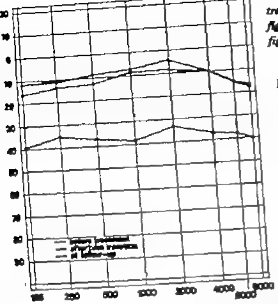
At the follow up examination the audiometric hearing test was carried out on 16 patients and a total of 29 ears The mean air conduction threshold at speech frequencies was 11.5 dB (S.D 9 7) The improvement from the preoperative value was 18 1 dB (the difference was statistically highly significant, $p < 0\ 001$) and deterioration from the immediate postoperative value was 1.5 dB (the difference was not statistically significant) (Fig 9) The youngest of the patients tested was 3 years old and the mean age was 9 2 years.

4.2.2.4 The cleft palate patients

The tympanostomy group contained 10 operated cleft palate patients On admission the hearing of 3 patients and a total of 6 ears had been tested The mean air conduction threshold at speech frequencies was 36 1 dB (S D 9 2) the corresponding bone conduction threshold 2.9 dB (S D 3.3) and the mean air bone gap 33 2 dB.



g. 10. Mean audiogram (air conduction) of the cleft late patients treated with tympanostomy tubes, on lmission (6 ears) 1 month after tube insertion (6 ars), and at follow-up (10 ears)

The youngest patient tested was 7 years old, and the mean age was 7 7 years.

At the follow-up examination the audiometric hearing test was carried out on 5 patients representing 10 ears. Three patients (6 ears) still had the tubes in position. The mean air conduction threshold at speech frequencies was 6.7 dB (S D 5.2) Compared with the preoperative value the mean air conduction threshold had improved by 29 4 dB (the difference was statistically highly significant, $p<0.001$) (Fig. 10) The youngest of the patients tested was 4 years old and the mean age was 9.2 years.

4 2.3. *Patients treated without tympanostomy*

On admission, the hearing of 10 patients representing 18 ears could be measured by audiometry (Table XIX) The mean air conduction threshold at speech frequencies was 22.8 dB (S D 12.1) the corresponding bone conduction threshold —2.0 dB (S.D 4.2) and the mean air-bone gap 24.8 dB. The youngest patient tested by audiometry was 4 years old, and the mean age of the group was 7 9 years.

conduction threshold had deteriorated by 0 6 dB from the preoperative value (the difference was not statistically significant) The mean air bone gap had diminished by 16 8 dB from the preoperative value

On admission for treatment the air conduction threshold at speech frequencies exceeded 30 dB on 35 ears (39 8 %) (Fig 7) but at the follow up examination in only one (0 7 %) (Fig 8)

4 2.2.3 Tubes in position at the follow up examination

On admission the hearing of 15 patients, and a total of 28 ears had been tested. The mean air conduction threshold at speech frequencies in the whole group was 29 6 dB (S D 12.4) the corresponding mean bone conduction threshold 3 2 dB (S D 4 6) and the mean air bone gap 26 4 dB The youngest of the patients tested was 4 years old, and the mean age was 7 1 years.

About 1 month after the insertion of the tubes a hearing test was made on 19 patients representing 34 ears. The mean air conduction threshold at speech frequencies was 10 0 dB (S.D 7 2) it had improved by 19 6 dB from the preoperative value (the difference was statistically highly significant $p < 0\ 001$) The youngest of the patients tested was 4 years old and the mean age was 7.3 years

At the follow up examination the audiometric hearing test was carried out on 16 patients and a total of 29 ears. The mean air conduction threshold at speech frequencies was 11.5 dB (S D 9 7) The improvement from the preoperative value was 18 1 dB (the difference was statistically highly significant $p < 0\ 001$) and deterioration from the immediate postoperative value was 1.5 dB (the difference was not statistically significant) (Fig 9) The youngest of the patients tested was 3 years old, and the mean age was 9.2 years.

4 2.2.4 The cleft palate patients

The tympanostomy group contained 10 operated cleft palate patients On admission the hearing of 3 patients and a total of 6 ears had been tested. The mean air conduction threshold at speech frequencies was 36 1 dB (S.D 9 2) the corresponding bone conduction threshold 2.9 dB (S D 3.3) and the mean air-bone gap 33 2 dB

5. DISCUSSION

According to Lumio (1957) Juselius (1958) and Watson (1969) chronic secretory otitis media is the most common cause of impaired hearing in childhood. Watson states that this disease accounted for 81 % of the impaired hearing among 5-year olds but 6 % among 13-year olds. According to several earlier studies the incidence of chronic secretory otitis media is highest among children aged 4—8 years (Hoople, 1950; Armstrong, 1957 Lemon, 1962; Kersley & Wickham, 1966; Hussl 1973a) The present material differs from the above in that the group of children under 1 year was numerically the greatest. The second largest age group was 7—8 years, the age at which children start school and are subjected to systematic hearing tests. These findings support Hussl's (1973a) idea that chronic secretory otitis media also occurs among the younger age groups but due to its slight symptoms is less frequently diagnosed. The diagnosis in an uncooperative child is successful only if the routine ear examination is made with Siegle's pneumatic speculum and if diagnostic paracentesis is made in suspected cases (Hussl 1973a)

The studies of recent years seem to have conclusively shown that chronic secretory otitis media is a result of a postinflammatory increase of the mucus-producing elements of the middle ear and the accompanying dysfunction of the Eustachian tube (Bendek, 1963 Friedman, 1963 Sadé, 1966 Lim & Hussl, 1969; Tos & Bak Pedersen, 1972, 1973 Bak Pedersen & Tos, 1971 1973 Bernstein et al. 1973, Palva et al. 1974a, 1974b) On the basis of the above studies it seems plausible that omission of paracentesis in acute otitis media is contributory to the increase of chronic secretory otitis media in the era of antibiotics (Sochs, 1956; Armstrong, 1957 Friedman, 1963; Palva & Karma, 1973 Palva et al. 1974a, 1974b) In the present material of 181 patients, the annual number of those seeking treatment has grown continuously This, however does not directly indicate any true increase in chronic secretory otitis media, for in earlier years the majority of patients were treated at outpatient clinics by repeated paracentesis, and these patients are not at all covered by the present study

In the present material the sex distribution in chronic secretory otitis media was similar to that reported by Eagle (1946) Solow (1958) and Draper (1967) — c 60 % boys and 40 % girls. It is difficult to pinpoint the reason for the overrepresentation of boys. In Solow's opinion the distribution is the same as that of allergy before puberty This does not hold good concerning the present material where respiratory allergy was diagnosed in only 5 patients (2.8 %); admittedly eosinophils were not sought systematically The share of allergy in this material was markedly smaller than in Jordan's (1952) material, but agreed with the findings reported by Lemon (1962) and Kersley & Wickham (1966)

The adenoids, the infections of the nose and nasal sinuses, and changes in the tubal orifice have been found to play a part in the etiology of chronic secretory otitis media. Furthermore, cleft palate patients have been found to have a remarkably high disposition to the disease (Stool & Randall, 1967) In the present series, 27 patients (14.9 %) were found to have sinusitis, 8 patients (4 4 %) a pathological nasopharyngeal status, and 10 patients (5.5 %) an operated or unoperated cleft palate on admission for treatment. Very large-sized adenoids were seen in 37 patients (20 4 %). Dawes (1970) and Manston & Fagan (1972) are of the opinion that there is no evidence to support "adenoidectomy"

10 7 dB (the difference was statistically highly significant p<0 001) The bone conduction threshold had deteriorated by 3 9 dB (the difference was statistically not significant) (Fig 11) and the mean air bone gap had diminished by 14 6 dB

ears on admission (*18* ears) and at follow-up (*27* ear

5. DISCUSSION

According to Lumio (1957) Jusélius (1958) and Watson (1969) chronic secretory otitis media is the most common cause of impaired hearing in childhood. Watson states that this disease accounted for 81 % of the impaired hearing among 5-year olds but 0 % among 13-year olds. According to several earlier studies the incidence of chronic secretory otitis media is highest among children aged 4—8 years (Hoople, 1950; Armstrong, 1957 Lemon 1962, Kersley & Wickham, 1966; Hussl, 1973a) The present material differs from the above in that the group of children under 1 year was numerically the greatest. The second largest age group was 7—8 years, the age at which children start school and are subjected to systematic hearing tests. These findings support Hussl's (1973a) idea that chronic secretory otitis media also occurs among the younger age groups but due to its slight symptoms is less frequently diagnosed. The diagnosis in an uncooperative child is successful only if the routine ear examination is made with Siegle's pneumatic speculum, and if diagnostic paracentesis is made in suspected cases (Hussl, 1973a)

The studies of recent years seem to have conclusively shown that chronic secretory otitis media is a result of a postinflammatory increase of the mucus-producing elements of the middle ear and the accompanying dysfunction of the Eustachian tube (Bendek, 1963, Friedman 1963 Sadé 1966, Lim & Hussl, 1969; Tos & Bak Pedersen, 1972, 1973 Bak Pedersen & Tos, 1971 1973 Bernstein et al. 1973 Palva et al. 1974a, 1974b) On the basis of the above studies it seems plausible that omission of paracentesis in acute otitis media is contributory to the increase of chronic secretory otitis media in the era of antibiotics (Suehs, 1956; Armstrong, 1957 Friedman, 1963 Palva & Karma, 1973 Palva et al. 1974a, 1974b) In the present material of 181 patients, the annual number of those seeking treatment has grown continuously This, however does not directly indicate any true increase in chronic secretory otitis media, for in earlier years the majority of patients were treated at outpatient clinics by repeated paracentesis, and these patients are not at all covered by the present study

In the present material the sex distribution in chronic secretory otitis media was similar to that reported by Eagle (1946) Solow (1958) and Draper (1967) — c. 60 % boys and 40 % girls. It is difficult to pinpoint the reason for the overrepresentation of boys. In Solow's opinion the distribution is the same as that of allergy before puberty This does not hold good concerning the present material where respiratory allergy was diagnosed in only 5 patients (2.8 %); admittedly eosinophils were not sought systematically The share of allergy in this material was markedly smaller than in Jordan's (1952) material, but agreed with the findings reported by Lemon (1962) and Kersley & Wickham (1966)

The adenoids, the infections of the nose and nasal sinuses, and changes in the tubal orifice have been found to play a part in the etiology of chronic secretory otitis media. Furthermore, cleft-palate patients have been found to have a remarkably high disposition to the disease (Stool & Randall, 1967) In the present series, 27 patients (14.9 %) were found to have sinusitis, 8 patients (4 4 %) a pathological nasopharyngeal status, and 10 patients (5.5 %) an operated or unoperated cleft palate on admission for treatment. Very large-sized adenoids were seen in 37 patients (20 4 %) Dawes (1970) and Mawson & Fagan (1972) are of the opinion that there is no evidence to support "adenoidectomy"

as a primary form of treatment but the present author finds that adenotomy must be made and the infections of the nose and nasopharynx treated before tube theraby is instituted Mawson & Fagan first carried out myringotomy and aspiration on their patients and if aspiration was still positive a second time they inserted the tubes In the present material myringotomy and aspiration were carried out first and the next step if required was adenotomy After this the patients were given a weekly check up and, if necessary paracentesis and aspiration were performed Only if the disease failed to heal with this treatment were tubes inserted The mean interval from the diagnosis of chronic secretory otitis media to the insertion of tympanostomy tubes was 8.5 months The interval must be considered too long· on the other hand a number of patients were symptom free for several months during this interval. The best policy seems to be if the paracentesis made weekly after the adenotomy is positive on 2—3 occasions to insert the tympanostomy tubes This of course does not apply to cleft palates and other special cases in which the insertion of the tubes is indicated as soon as the disease has been diagnosed.

The present series included 2 patients whose tubal orifices were badly strictured after an earlier adenotomy In both patients the tympanostomy tube therapy lasted more than 24 months and after every extrusion of the tubes the disease recurred. To avoid this adenotomy should always be carried out under general anaesthesia and under visual control taking special care not to damage the Eustachian tubes.

According to Turner (1967) the mean period during which a polyethylene tube remained ventilating was 10 9 weeks against 24 weeks for silastic and teflon tubes. In the material published by Mawson & Fagan (1972) the mean survival of Shephard's teflon tubes was 6 6 months In the present study most patients were fitted with polyethylene tubes of our own make only a few having ready-made silastic tubes. The mean survival of 511 tympanostomy tubes was 7 0 months. As a rule, tympanostomy tubes should not be removed but allowed to be spontaneously extruded.

It used to be a common belief that the middle ear effusion in chronic secretory otitis media was sterile (Jordan 1949 Ivstamm 1954 Tönder & Gundersen 1971) In the present material, 322 bacterial samples (198 ears) were collected in connection with the insertion of the tube and 71 (22 %) of them were positive. The most common bacteria were Hemophilus influenzae, Staphylococcus aureus and Staphylococcus albus Bernstein & Hayes (1971) reported similar findings on their material. The cause of the bacteriological sterility is apparently not so much the poor culture techniques or viral etiology as the preceding antibiotic therapy and the bactericidal and bacteriostatic effect of the middle ear effusion (Siirala & Lahikainen, 1952) deriving from the IgA secreted by the middle ear mucosa (Bernstein et al 1972) According to Siirala & Lahikainen children's middle ear effusion had no effect against Hemophilus influenzae. A middle ear infection in the course of tympanostomy tube therapy has generally been considered a minor problem (Hussl 1973b) but in the present material discharge occurred during tube therapy in 41 % of the ears and if Hemophilus influenzae grew in the bacterial sample taken in connection with tube insertion, there was discharge in 79 % Mastoidectomy had to be carried out on 15 ears for persistent discharge and radiographic mastoiditis while the others healed with conservative therapy This susceptibility to infection is probably partly due to poor social conditions and the instability of the climate.

According to Politzer (1878) and Zechner (1969) chronic secretory otitis media if left untreated leads to chronic adhesive otitis media. In the present series, both eardrums of one patient were found to be adhesive at the follow up examination. This patient treated without tympanostomy had had purulent discharge from both ears. Treatment had been neglected and the result was bilateral adhesive otitis and a poor hearing result. This case supports the assumption by Ojala (1953) concerning the etiology of adhesive otitis

According to Ojala, recurrent infections exceeding a given minimum and, additionally a deteriorated drainage are necessary before adhesive otitis can develop. Adhesive otitis media was not seen in any of the ears treated with tympanostomy, although in 2 ears (0.7 %) a small area of the drum adhered to the promontorium. In these ears, also, there had been purulent discharge that had not been treated adequately.

According to Zalin (1963), chronic secretory otitis media is an intermediate stage in the development of cholesteatoma, and Jordan (1963) reported on 11 cases in which cholesteatoma developed during the course of treatment for chronic secretory otitis media. The 165-patient series of MacKinnon (1971) contained 8 cholesteatomas. In the present material of 181 patients representing 313 ears the follow up examination disclosed 4 cholesteatomas (1.4 %), of which 2 (0.7 %) can be considered a complication of tube therapy. During the tube therapy these 2 ears showed a purulent discharge which was not treated in any way. As a result of prolonged discharge both ears developed a marginal perforation and later a cholesteatoma. One patient, during the tympanostomy tube therapy, developed an attic cholesteatoma in both ears as the result of retraction of Shrapnell's membrane.

A complication more frequent than cholesteatoma in the present material was persistent perforation. At the follow-up examination, 12 perforations were recorded, and additionally myringoplasty had been carried out in one ear for persistent perforation (total 4.5 %). The number of perforations considerably exceeded that reported by MacKinnon (1971) and by Mawson & Fagan (1972). The large number of perforations in the present series was apparently a result of the high rate of discharge. On the other hand, the purpose of tympanostomy therapy is to create a persistent perforation, and hence perforation should actually not be considered a complication. Closing the perforation operatively is not meaningful as long as there is a risk of the disease recurring.

In the material of Mawson & Fagan (1972) the most common drum change after tympanostomy tube therapy was tympanosclerosis (30 %). The next most common were retraction of the drum (21 %), atelectasis (9 %) and a visible tympanostomy scar (5 %). In their material only 18 % of the drums were normal at the follow-up examination. In the present material, 44.8 % of the drums treated with tympanostomy were normal or nearly normal in the follow-up examination, 10.0 % were tympanosclerotic, 7.6 % pseudomembranous, 5.2 % scarred, 3.0 % atrophic, 2.1 % retracted, and 2.1 % adhered to the head of the stapes. The tympanostomy tubes were in position and ventilating in 22.1 %, a recurrence was seen in 3.1 %, purulent discharge from the tube in 1.7 % and complications in 7.6 %. The large proportion of normal drums in the present series compared with the above reports was probably rather a result of different criteria than better therapeutic results. In the group treated without tympanostomy 74.2 % of the drums were normal at the follow-up examination and 25.8 % were abnormal, 2 of the latter (6.5 %) were adhesive.

Hearing loss in chronic secretory otitis media varies greatly. Cohen & Sadé (1972) quoted the limit values of 0 dB and 50 dB for the threshold of the speech frequencies. In the reports of Silverstein et al. (1966), Cohen & Sadé (1972), Kilby et al. (1972), Mawson & Fagan (1972) and Hussl (1973b) the mean hearing loss at speech frequencies was 25—40 dB. In the present material the mean hearing loss at speech frequencies was 27.6 dB, ranging from 5 to 70 dB, before treatment. The 2000 Hz air conduction threshold was statistically significantly ($p < 0.01$) better than that of 250 Hz, and highly significantly ($p < 0.001$) better than those of the other frequencies. The result was the same as that reported by Harbert & Mendelsohn (1970) and shows that 2000 Hz is the optimum frequency of the human ear in conductive defects of this type. No corresponding difference was observable in bone conduction hearing.

After the insertion of tubes the mean air conduction threshold in the present material (147 ears) was 9.5 dB. If the hearing fails to

as a primary form of treatment but the present author finds that adenotomy must be made and the infections of the nose and nasopharynx treated before tube theraby is instituted Mawson & Fagan first carried out myringotomy and aspiration on their patients and if aspiration was still positive a second time they inserted the tubes In the present material myringotomy and aspiration were carried out first and the next step if required was adenotomy After this the patients were given a weekly check up and, if necessary paracentesis and aspiration were performed Only if the disease failed to heal with this treatment were tubes inserted The mean interval from the diagnosis of chronic secretory otitis media to the insertion of tympanostomy tubes was 8.5 months. The interval must be considered too long on the other hand a number of patients were symptom free for several months during this interval The best policy seems to be if the paracentesis made weekly after the adenotomy is positive on 2—3 occasions to insert the tympanostomy tubes This of course does not apply to cleft palates and other special cases in which the insertion of the tubes is indicated as soon as the disease has been diagnosed

In the group treated without tympanostomy 74.2 % of the drums were normal *at the follow up examination* and 25.8 % were abnormal, 2 *of the* latter (6.5 %) were adhesive.

Hearing loss in chronic secretory otitis media varies greatly. Cohen & Sadé (1972) quoted the limit values of 0 dB and 50 dB for the threshold of the speech frequencies. In the reports of Silverstein et al. (1966), Cohen & Sadé (1972), Kilby et al. (1972), Mawson & Fagan (1972) and Huttl (1973b) the mean hearing loss at speech frequencies was 25—40 dB. In the present material the mean hearing loss at speech frequencies was 27.6 dB ranging from 5 to 70 dB, *before treatment.* The *2000 Hz* air *conduction* threshold was *statistically significantly* ($p < 0.01$) better than that of 250 Hz, and *highly significantly* ($p < 0.001$) better than those *of the other* frequencies. The result was the same as that reported by Harbert & Mendoza (1970) and shows that 2000 *Hz* is the optimum frequency of the *human* ear *in conductive defects* of this type. No *corresponding difference* was *observable* in bone *conduction* hearing.

After the *insertion of tubes* the mean air conduction threshold in the present material (147 ears) was 9.5 dB. *If* the hearing falls to

return to the normal level on tube insertion there is reason to suspect that the loss of hearing has some other cause than chronic secretory otitis media In one ear of the material the cause of the hearing loss was found to be tympanal anomaly and a bilateral tympanal anomaly was suspected in one patient.

At the follow up study the mean air conduction threshold of the total material was 12.3 dB and in 8 8 % of the ears the mean threshold of the speech frequencies exceeded 30 dB Accordingly the threshold of the speech frequencies for ears treated with tubes was at the follow up 11.3 dB or 1 8 dB higher than immediately after the insertion of the tubes The corresponding difference in the ears in which chronic secretory otitis media at the follow up was found to have healed was also 1 8 dB Although the difference is not statistically significant it probably gives a hint of drum changes produced by the tube therapy In the group of the ears treated without tympanostomy the mean air conduction threshold at speech frequencies was 22 8 dB on admission and 12.1 dB at the follow up The threshold had improved during treatment by 10 7 dB which is 5 1 dB less than in the group treated with tubes It is possible to obtain good results even without tubes, but the weekly paracentesis under general anaesthesia as suggested by Senturia (1958) is practically impossible in our circumstances, and furthermore unpleasant for the children. The risk always accompanying anaesthesia should not be underestimated. In addition to all of this the improvement of hearing achieved by paracentesis and aspiration may be of only a few days duration

The hearing results obtained are similar to those reported by Mawson & Fagan (1972) but definitely better than those reported by Kilby et al (1972) on a material of patients treated by a single unilateral paracentesis at the beginning of treatment and by insertion of a tympanostomy tube in the contralateral ear also only once at the beginning of treatment In both of Kilby s groups the air conduction threshold at speech frequencies was c 16 dB after the follow up period of 2 years.

The effectivity of the tympanostomy tube therapy which according to Palva et al (1974a, 1974b) is based on the drying effect of the air on the mucosa causing degeneration of glands and normalization of mucosa on one hand, and on the equalization of the negative pressure of the middle ear on the other appears to be indisputable in the treatment of chronic secretory otitis media. The permanent improvement of hearing achievable by means of the tympanostomy tubes is of decisive importance to children who are at the age when learning is most essential for their development.

6 CONCLUSIONS

Chronic secretory otitis media is the most common cause of hearing loss in children, and its increased incidence is partly a result of improved diagnosis while a part represents a true increase.

In most patients the onset of chronic secretory otitis media occurs before school age and in many at an age of less than one year.

The cause of chronic secretory otitis media is, on the one hand, untreated or inadequately treated acute otitis media, and on the other, a relative dysfunction of the Eustachian tube. Cleft palate patients form a risk group that requires regular otological observation from birth onwards.

In chronic secretory otitis media, the effusion is the final result of mucous gland activity released by infection. The effusion is mostly sterile. The sterility is attributable to a preceding antibiotic therapy or to the bactericidal and bacteriostatic effect of the effusion itself. Chronic secretory otitis media alone apparently does not lead to adhesive otitis but only if combined with recurrent suppurative infection.

The hearing loss in chronic secretory otitis media varies greatly, but is in most cases so great that it adversely affects the child's development and his progress in school.

Hearing improvement following paracentesis is of short duration. After tympanostomy the hearing returns to the normal level and remains there unless the disease recurs after the extrusion of the tubes.

The removal of tympanostomy tubes is usually not advisable. The best thing is to let the tubes be spontaneously extruded and then observe whether the disease recurs. Most cases of chronic secretory otitis media heal with a tube therapy of less than a year's duration.

To keep track of complications and recurrences, the patients must be seen often enough during therapy and during at least one year after the tube therapy.

Discharge is a common complication during tube therapy and it is apparently dependent on social conditions and the local climate.

Drum changes such as tympanosclerosis, formation of pseudomembrane, cicatrization and atrophy, are common after tympanostomy tube therapy, but they are of minor importance from the hearing level point of view.

Persistent perforations are more often caused by discharge complications than by the normal extrusion of tubes.

Possible complications arising in connection with tympanostomy tube therapy are marginal perforation and cholesteatoma. Also, chronic secretory otitis media may, even in the course of tube therapy, lead to the development of cholesteatoma of the attic.

return to the normal level on tube insertion there is reason to suspect that the loss of hearing has some other cause than chronic secretory otitis media. In one ear of the material the cause of the hearing loss was found to be tympanal anomaly and a bilateral tympanal anomaly was suspected in one patient.

At the follow up study the mean air conduction threshold of the total material was 12.3 dB and in 8 8 % of the ears the mean threshold of the speech frequencies exceeded 30 dB Accordingly the threshold of the speech frequencies for ears treated with tubes was at the follow up 11.3 dB or 1 8 dB higher than immediately after the insertion of the tubes. The corresponding difference in the ears in which chronic secretory otitis media at the follow up was found to have healed was also 1 8 dB Although the difference is not statistically significant it probably gives a hint of drum changes produced by the tube therapy In the group of the ears treated without tympanostomy the mean air conduction threshold at speech frequencies was 22 8 dB on admission and 12.1 dB at the follow up The threshold had improved during treatment by 10 7 dB which is 5 1 dB less than in the group treated with tubes It is possible to obtain good results even without tubes but the weekly paracentesis under general anaesthesia as suggested by Senturia (1958) is practically impossible in our circumstances, and furthermore unpleasant for the children. The risk always accompanying anaesthesia should not be underestimated In addition to all of this the improvement of hearing achieved by paracentesis and aspiration may be of only a few days duration

The hearing results obtained are similar to those reported by Mawson & Fagan (1972) but definitely better than those reported by Kilby et al (1972) on a material of patients treated by a single unilateral paracentesis at the beginning of treatment and by insertion of a tympanostomy tube in the contralateral ear also only once at the beginning of treatment. In both of Kilby s groups the air conduction threshold at speech frequencies was c. 16 dB after the follow up period of 2 years

The effectivity of the tympanostomy tube therapy which according to Paiva et al (1974a 1974b) is based on the drying effect of the air on the mucosa causing degeneration of glands and normalization of mucosa on one hand and on the equalization of the negative pressure of the middle ear on the other appears to be indisputable in the treatment of chronic secretory otitis media The permanent improvement of hearing achievable by means of the tympanostomy tubes is of decisive importance to children who are at the age when learning is most essential for their development.

6 CONCLUSIONS

The permanent improvement of hearing achievable by means of the tympanostomy tubes is of decisive importance to children who are at the age when learning is most essential for their development.

6 CONCLUSIONS

Chronic secretory otitis media is the most common cause of hearing loss in children, and its increased incidence is partly a result of improved diagnosis while a part represents a true increase.

In most patients the onset of chronic secretory otitis media occurs before school age and in many at an age of less than one year.

The cause of chronic secretory otitis media is, on the one hand, untreated or inadequately treated acute otitis media, and on the other a relative dysfunction of the Eustachian tube. Cleft palate patients form a risk group that requires regular otological observation from birth onwards.

In chronic secretory otitis media, the effusion is the final result of mucous gland activity released by infection. The effusion is mostly sterile. The sterility is attributable to a preceding antibiotic therapy or to the bactericidal and bacteriostatic effect of the effusion itself. Chronic secretory otitis media alone apparently does not lead to adhesive otitis but only if combined with recurrent suppurative infection.

The hearing loss in chronic secretory otitis media varies greatly but is in most cases so great that it adversely affects the child's development and his progress in school.

Hearing improvement following paracentesis is of short duration. After tympanostomy the hearing returns to the normal level and remains there unless the disease recurs after the extrusion of the tubes.

The removal of tympanostomy tubes is usually not advisable. The best thing is to let the tubes be spontaneously extruded and then observe whether the disease recurs. Most cases of chronic secretory otitis media heal with a tube therapy of less than a year's duration.

To keep track of complications and recurrences, the patients must be seen often enough during therapy and during at least one year after the tube therapy.

Discharge is a common complication during tube therapy and it is apparently dependent on social conditions and the local climate.

Drum changes such as tympanosclerosis, formation of pseudomembrane, cicatrization and atrophy are common after tympanostomy tube therapy but they are of minor importance from the hearing level point of view.

Persistent perforations are more often caused by discharge complications than by the normal extrusion of tubes.

Possible complications arising in connection with tympanostomy tube therapy are marginal perforation and cholesteatoma. Also, chronic secretory otitis media may even in the course of tube therapy lead to the development of cholesteatoma of the attic.

7 SUMMARY

A material of 181 children (323 ears) with chronic secretory otitis media covering the 7 year period of 1965—71 is presented. 164 children (290 ears) were treated with tympanostomy tubes and 17 children (33 ears) conservatively with paracentesis. The patients attended a follow up examination in 1972 when special attention was devoted to the complications produced by chronic secretory otitis media and tympa nostomy tube therapy and to hearing losses

The onset of the symptoms of chronic secretory otitis media had usually occurred before school age The largest number of patients were under 1 year of age (18 9 %) at the onset, but almost the same number were 7—8 years olds (14 6 %) who had just started school

A total of 511 tympanostomy tubes were inserted, and 322 bacterial samples (198 ears) were taken in connection with the insertion 251 of them (78 %) were negative and 71 (22 %) positive. The most common bacteria were Hemophilus influenzae Staphylococcus aureus and Staphylococcus albus.

Purulent discharge was seen to accompany 124 tube treatments (25 %) Mastoidectomy had to be carried out on 15 ears (5 8 %) for prolonged suppurative discharge and the radiographic ear finding

At the follow-up examination which was carried out on average 3 years 2 months after the institution of tube therapy the chronic secretory otitis media was found to have healed in 190 ears (65 5 %) In 64 ears (22 1 %) the tubes were still in position and the patients were symptom free. In 9 ears (3 1 %) the disease had recurred in 5 ears (1 7 %) there was purulent discharge through the tubes and 22 ears (7 6 %) showed complications caused by chronic secretory otitis media and tube therapy The most common complication was persistent perforation, found in 13 ears (4.5 %) Cholesteatoma had developed during treatment in 4 ears (1 4 %) and 2 of these were attic cholesteatomas (0.7 %) (both in the same patient) The eardrum of the ears in which chronic secretory otitis media had healed was normal in 130 cases (68.4 %) and abnormal in 60 (31 6 %) The most common abnormal finding was tympanosclerosis.

In the conservatively treated group the eardrum status at the follow up examination was found to be normal in 23 ears (74 2 %) and abnormal in 8 ears (25 8 %) The worst drum changes were in a patient both of whose drums were adhesive and who had an air conduction threshold of 51 7 dB at speech frequencies in both ears

On admission for treatment the mean air conduction threshold (the mean value of 500 1000 and 2000 Hz) of the total material (161 ears) was 27 6 dB and at the follow-up examination (238 ears) 12.3 dB. The mean air conduction threshold improved during therapy by an average of 15.3 dB and the mean air bone gap diminished by 17.3 dB

In patients treated with tympanostomy tubes the mean air conduction threshold at speech frequencies was on admission (134 ears) 27 1 dB after insertion of the tubes (147 ears) 9.5 dB and at the follow up examination (202 ears) 11.3 dB During treatment the mean air conduction threshold improved by 15 8 dB and the mean air bone gap diminished by 16 4 dB

In the ears treated without tympanostomy the mean air conduction threshold at speech frequencies was on admission (18 ears) 22.8 dB and the follow-up (27 ears) 12.1 dB During treatment the mean air conduction threshold improved by 10 7 dB and the mean air bone gap diminished by 14 6 dB

In the total material, on admission the mean

air conduction threshold at speech frequencies was better than 15 dB in 21 1 % and poorer than 30 dB in 37 9 % At the follow-up the threshold was better than 15 dB in 76.5 % of the ears and poorer than 30 dB in 8.8 % The air conduction threshold at speech frequencies was found to be bilaterally poorer than 30 dB in 4 patients. Of these, 2 had a perceptive hearing loss exceeding 30 dB in both ears one had a manifest bilateral tympanal anomaly and the fourth a bilateral adhesive otitis as the result of neglected treatment.

7 SUMMARY

A material of 181 children (323 ears) with chronic secretory otitis media covering the 7 year period of 1965—71 is presented 164 children (290 ears) were treated with tympanostomy tubes and 17 children (33 ears) conservatively with paracentesis The patients attended a follow up examination in 1972, when special attention was devoted to the complications produced by chronic secretory otitis media and tympa nostomy tube therapy and to hearing losses.

8 ACKNOWLEDGEMENTS

My teacher Professor Tauno Palva, M D former Head of the Department of Otolaryngology at Oulu University and present Head of the Department of Otolaryngology at Helsinki University suggested this research project to me His expert advice throughout the work helped me to bring it to a conclusion. I wish to express my deep gratitude to him

I am also greatly indebted to Associate Professor Antti Palva, M D Acting Head of the Department of Otolaryngology at Oulu University for his excellent guidance in the final phases of the work.

To Docent Juhani Kärjä M D go my sincere thanks for the great expertise with which he advised me during the preparation of the manuscript

My gratitude is also due to Docent Aarno Kohonen M D for helpful suggestions during the final preparatory stages of this work.

I wish to thank Mr Heikki Nieminen and Mrs Seija Nieminen for preparation of the illustrations required for the book Mrs Aino Janatuinen for carrying out the audiometric tests Mr Jorma Pietilä for the statistical treatment of the results, Mrs Hilkka Kontiopää, M.A and Mrs Barbara Rikberg for translation of the manuscript and Mrs Pirkko Orell for help in collecting literature

My study was financially supported by the Oulu Research Council for Medical Sciences, by Korvatautien Tutkimussäätiö and by the State Research Council for Medical Sciences

8 ACKNOWLEDGEMENTS

My teacher Professor Tauno Palva, M D former Head of the Department of Otolaryngology at Oulu University and present Head of the Department of Otolaryngology at Helsinki University suggested this research project to me. His expert advice throughout the work helped me to bring it to a conclusion I wish to express my deep gratitude to him.

I am also greatly indebted to Associate Professor Antti Palva M D Acting Head of the Department of Otolaryngology at Oulu University for his excellent guidance in the final phases of the work

To Docent Juhani Kärjä, M D go my sincere thanks for the great expertise with which he advised me during the preparation of the manuscript.

My gratitude is also due to Docent Aarno Kohonen M D for helpful suggestions during the final preparatory stages of this work

I wish to thank Mr Heikki Nieminen and Mrs Seija Nieminen for preparation of the illustrations required for the book Mrs Aino Janatuinen for carrying out the audiometric tests, Mr Jorma Pietilä for the statistical treatment of the results Mrs Hilkka Kontiopää, M A and Mrs Barbara Rikberg for translation of the manuscript and Mrs Pirkko Orell for help in collecting literature.

My study was financially supported by the Oulu Research Council for Medical Sciences, by Korvatautien Tutkimussäätiö and by the State Research Council for Medical Sciences

I Introduction

The spread of infection from the nasal cavity into the paranasal sinuses is a common complication of colds. It has been estimated that II per cent of persons contract sinusitis (van Dishoeck, 1961). The sinus most often clinically affected is the maxillary sinus.

In addition to anatomical investigations, earlier research dealt with the bacteriology of sinusitis; only recently have investigations of the function of the sinus and its ostium gained interest, this despite the fact that the first observation on the patency of the ostium was made as early as 1877 by Braune & Clasen. They observed that pressure changes produced by blowing air into the trachea of a cadaver were transmitted into the maxillary sinuses. Later Döderlein (1932) reported that these pressure changes inside the sinus depend on the intensity of respiration, while Proetz (1932) and Kerekes (1934) proved that respiratory pressure changes inside the sinuses and the nasal cavity correspond to each other when the ostium is open. However it was not until much later that patency tests based on this comparison were developed. In 1965 Drettner and in 1968 Cottle presented their patency tests. Like Proetz, Drettner performed the pressure recordings simultaneously using two manometers. Cottle used both simultaneous and consecutive recordings.

Another test of ostial function is measurement of ostial resistance. This method probably originates from the observation that different degrees of resistance can be felt even by hand at sinus irrigation. *Flottes et al.* (1960) performed their ostial resistance measurements by injecting air into the sinus and measuring the pressure that opened the ostium. Drettner (1965a) described a technique of measuring ostial resistance by using saline irrigation. He recorded the least amount of airpressure that made the irrigation fluid flow through the ostium into the nasal canal.

The patency test seems to have gained wider acceptance in clinical practice than resistance measurement, which was considered, for example by Zippel & Maier (1968), to have only relative value in practice.

I Introduction

The spread of infection from the nasal cavity into the paranasal sinuses is a common complication of colds. It has been estimated that five per cent of persons contract sinusitis (van Dishoeck, 1961). The sinus most often clinically affected is the maxillary sinus.

In addition to anatomical investigations, earlier research dealt with the bacteriology of sinusitis; only recently have investigations of the function of the sinus and its ostium gained interest, this despite the fact that the first observation on the patency of the ostium was made as early as 1877 by Braune & Clasen. They observed that pressure changes produced by blowing air into the trachea of a cadaver were transmitted into the maxillary sinuses. Later Doderlein (1932) reported that these pressure changes inside the sinus depend on the intensity of respiration, while Proetz (1932) and Herckes (1934) proved that respiratory pressure changes inside the sinuses and the nasal cavity correspond to each other, when the ostium is open. However it was not until much later that patency tests based on this comparison were developed. In 1965 Drettner and in 1968 Cottle presented their patency tests. Like Proetz, Drettner performed the pressure recordings simultaneously using two manometers. Cottle used both simultaneous and consecutive recordings.

Another test of ostial function is measurement of ostial resistance. This method probably originates from the observation that different degrees of resistance can be felt even by hand at sinus irrigation. Flottes et al. (1960) performed their ostial resistance measurements by injecting air into the sinus and measuring the pressure that opened the ostium. Drettner (1965a) described a technique of measuring ostial resistance by using saline irrigation. He recorded the least amount of overpressure that made the irrigation fluid flow through the ostium into the nasal canal.

The patency test seems to have gained wider acceptance in clinical practice than resistance measurement, which was considered, for example by Zippel & Maier (1968), to have only relative value in practice.

II The aim of the study

This study was undertaken in order to investigate the relation of ostial function to clinical observations. A study in some detail of ostial function tests, the patency test and resistance measurement appeared necessary. Furthermore, possible changes in ostial function during the course of acute maxillary sinusitis were followed.

The results were treated in a way that would enable answers to the following questions to be attempted.

1. Can the investigated series be considered typical, as compared with earlier investigations on the etiology of the infection?
2. Is there any relation between the ache symptom and ostial patency and resistance to recovery?
3. Is there any relation between the x ray findings and the results of the ostial function tests?
4. How should the criteria of a patent ostium be determined when the pressure changes are recorded consecutively?
5. Is a certain phase or procedure in connection with the maxillary sinus puncture preferable in determining ostial patency?
6. What is the importance of using sniffing and blowing in connection with a patency test?
7. Should ostial resistance be measured before or after irrigating the sinus?
8. What are the alterations of ostial patency in sinusitis?
9. What are the changes of resistance in sinusitis?

III Literature review

A. Ostial anatomy

There are variations in the diameter and length of the ostium. According to the investigations of Zuckerkandl (1893), Oppikofer (1906) and Schaeffer (1920), the diameter of the ostium varies from 1 to 22 mm. Aust & Drettner (1974) ascertained that the mean functional diameter of the ostium in healthy persons is 2.4 mm. Simon (1939), who called the ostium a canal, stated its length to be ≧ 3 mm in 83 % of cases, average length being 5.5 mm. According to Wagemann (1964) the length of the ostium is usually from 3 to 8 mm.

Accessory ostia between the maxillary sinus and the nasal cavity have been reported by Zuckerkandl in 10 %, by Oppikofer in 11 %, by Schaeffer in 44 %, by Myerson (1932) in 3 % and by van Alyea (1936) in 23 % of cases.

Zange (1940) stated that "Schwellgewebe" occurs not only in the turbinates, but also in the ostial area. He considered that this, on the one hand, protects the sinus against the spread of infection, but, on the other hand, causes drainage hindrances in maxillary sinusitis, as well as ex vacuo headache.

B. Bacteriology and rȯntgenology of maxillary sinusitis

According to many earlier bacteriological investigations, the frequency of respiratory pathogens in sinus secretion varies greatly. Some of these results are illustrated in Table 1. The most common respiratory pathogens are the Diplococcus pneumoniae and the Haemophilus influenzae. The frequency of sterile secretions varies from 17.2 to 44.7 %.

Ballantyne & Rowe (1949) stated, in connection with 206 unselected cases with chronic maxillary sinusitis, that there was no retention of secretion inside the sinus where no changes in the mucosa could be roentgenologically demonstrated. Where the mucosa was thickened, secretion was present in less than 10 %, and in homogeneously clouded sinus in 86 % of the cases. According to Hinds's (1950) largely similar result the frequency of the cases with secretion was 10 % where the mucosa was thickened. In a retrospective investigation of 27[illegible] cases with maxillary sinusitis by Vuorinen et al. (1962) secretion was disclosed in 88 % where the sinus was homogeneously clouded, and in 54 % where its mucosa was thickened. These

II The aim of the study

This study was undertaken in order to investigate the relation of ostial function to clinical observations. A study in some detail of ostial function tests, the patency test and resistance measurement appeared necessary. Furthermore, possible changes in ostial function during the course of acute maxillary sinusitis were followed.

The results were treated in a way that would enable answers to the following questions to be attempted:

1. Can the investigated series be considered typical, as compared with earlier investigations on the etiology of the infection?
2. Is there any relation between the ache symptom and ostial patency and resistance to recovery?
3. Is there any relation between the x-ray findings and the results of the ostial function tests?
4. How should the criteria of a patent ostium be determined when the pressure changes are recorded consecutively?
5. Is a certain phase or procedure in connection with the maxillary sinus puncture preferable in determining ostial patency?
6. What is the importance of using sniffing and blowing in connection with a patency test?
7. Should ostial resistance be measured before or after irrigating the sinus?
8. What are the alterations of ostial patency in sinusitis?
9. What are the changes of resistance in sinusitis?

D Ostial resistance

I measuring ostial resistance, Flottes et al. (1960) used ai they did not, ho ever recommend pressures exceeding the ambient atmospheric pressures ith more than 200 mm H_2O because f the risk f air embolism. On the other hand, *Soubeyrand (1964) pointed out* that in subacute maxillary sinusitis the resistance is below that alue in only 6—1. % f ases. Consequently Drettner (1965a) and Zippel & Meyer (1968) used fluid instead f air in their resistance measurements. Their methods of measuring were similar.

Zippel & Meyer stated that in healthy persons normal resistance aries from 100 to 250 mm H_2O; in acute maxillary sinusitis resistance is normal in every other case, but elevated in the rest. *Drettner pointed out that average* resistance in sinusitis is 310 mm H_2O. Where there is retention of antral secretion, resistance is 420 mm H_2O on erage, whereas it is 150 mm H_2O in cases without secretion. He reported that t recovery from sinusitis ostial resistance becomes normal.

Rantanen & Kortekangas (1971) showed that at diagnostic puncture ostial resistance in sinusitis is more than 135 mm H_2O in every third case and less than that in the rest. Where the ostium as patent or partially patent for respiration, no elevation in resistance was noted in this in estigation in 60 % of the cases. On the other hand, when the *ostium* was *obstructed* during respiration, resistance was less than 135 mm H_2O in 43.5 % f the cases.

investigators found retention of secretion inside the sinus in 6 % of cases with a normal x-ray finding. The corresponding results of McNeill (1963) were 83 %, 63 % and 20 % in an investigation of 150 cases with maxillary sinusitis.

Most of the above investigations illustrate the correlation between x-ray findings and the presence of secretion inside the sinus in maxillary sinusitis. In order to demonstrate the retention of secretion inside the sinus in cases where the antral mucosa is thickened, more projections than the ordinary three or four are required in x-raying. Axelsson et al. (1970) in their investigation of 107 cases with maxillary sinusitis, reported secretion roentgenologically demonstrated inside the sinus in 24 % of cases with mucous membrane thickening, whereas this could be disclosed in 60 % through irrigation. When they added the fifth projection, the occipitomental with head horizontal and the affected side downwards, to the four standard projections, secretion was roentgenologically demonstrated in 88 % of the cases in which the puncture had been positive.

C. Ostial patency

Braune & Clasen (1877) reported changes of sinus pressure in their blowing experiment. Later Döderlein (1932) reported a decrease and increase of respiratory pressure inside the sinus in connection with empyema. Herckes (1934) could not demonstrate these changes at the beginning of sinusitis, but they appeared at the recovery stage. After Proetz (1932) had observed that an open ostium transmits respiratory pressure changes from the nasal cavity into the sinus as unchanged, Flottes et al. (1960) stated that conclusions can be drawn about the ostial patency by comparing decrease and increase of respiratory pressures in the nasal cavity and the sinus.

Pressure measurements can be performed consecutively in the sinus and the nasal cavity or the nasopharynx. The disadvantage of these measurements is that the intensity of respiration continuously changes even in the same person. In order to eliminate this disadvantage simultaneous measurements have been used (Proetz, 1932, Drettner 1965b, Cottle 1968) in which decrease and increase of the respiratory pressure are measured simultaneously in the sinus and the nasal cavity or the nasopharynx. Drettner measured the pressures on both sides of the ostium by means of a trocar introduced into the sinus and a plastic catheter placed in the middle meatus on the same side. Cottle compared the pressure of the maxillary sinus with the pressure of the nasopharynx which he measured through a nozzle in the nostril opposite to the investigated side. Kortekangas (1970, 1974) proposed recording of the pressure difference between the maxillary sinus and the nasopharynx as part of the ostial patency test. In all the other methods, the deviation of pressure from the ambient atmospheric pressure is first measured, after which the pressure curves of the sinus and nasal cavity or the nasopharynx are mutually compared.

In acute sinusitis there are respiratory pressure changes inside the sinus in 23.2 %; in only 8.7 %, however, are the pressure changes identical in the nasal cavity and the sinus (Drettner 1965e). On the basis of these observations, Drettner divided the ostia into patent, partially obstructed and obstructed. He regarded the ostium as patent if, during respiration, the decrease and increase of pressure in the plastic catheter and the trocar corresponded to each other. When the pressure changes inside the sinus were less pronounced than those in the nasal cavity, the ostium was called partially obstructed. If there was no antral decrease or increase of the respiratory pressure, he regarded the ostium as obstructed. A partial obstruction can, according to Drettner, be caused by the ostium itself and also by the secretion that partially obstructs the ostium and/or the trocar. Rantanen & Kortekangas (1971) used the term partially patent for a partial obstruction. In a study comprising 36 maxillary sinusitis, an ostial obstruction was reported in 55.6 % at diagnostic puncture, but at the end of treatment in only one case.

In addition to respiratory pressures, Drettner (1965b) also used pressures produced by sniffing and blowing, when evaluating the ostial patency. He reported an ostial obstruction for sniff/blow pressures in acute maxillary sinusitis in 47.8 %, whereas sniffing and blowing opened an ostium obstructed for respiratory pressures in 25 % of the cases.

A valve phenomenon, earlier observed by Proetz (1932), Schmidtker (1932) and Herckes (1934), was reported by Drettner (1965e) in an obstructed ostium in 13.2 % of the cases. Later the valve phenomenon was analysed by Drettner (1967).

D. Ostial resistance

In measuring ostial resistance, Flottes et al. (1960) used air: they did not, however recommend pressures exceeding the ambient atmospheric pressures with more than 200 mm H_2O because of the risk of air embolism. On the other hand, Soubeyrand (1964) pointed out that in subacute maxillary sinusitis the resistance is below that value in only 8—12 % of cases. Consequently Drettner (1965a) and Zippel & Meier (1968) used fluid instead of air in their resistance measurements. Their methods of measuring were similar.

Zippel & Meier stated that in healthy persons normal resistance varies from 100 to 250 mm H_2O. In acute maxillary sinusitis resistance is normal in every other case, but elevated in the rest. Drettner pointed out that average resistance in sinusitis is 310 mm H_2O. Where there is retention of antral secretion, resistance is 420 mm H_2O on average, whereas it is 150 mm H_2O in cases without secretion. He reported that in recovery from sinusitis ostial resistance becomes normal.

Rantanen & Kortekangas (1971) showed that at diagnostic puncture ostial resistance in sinusitis is more than 135 mm H_2O in every third case and less than that in the rest. Where the ostium was patent or partially patent for respiration, no elevation in resistance was noted in this investigation in 60 % of the cases. On the other hand, when the ostium was obstructed during respiration, resistance was less than 135 mm H_2O in 43.6 % of the cases.

investigators found retention of secretion inside the sinus in 8 % of cases with a normal x-ray finding. The corresponding results of Mc Neill (1963) were 83 %, 63 % and 20 % in an investigation of 150 cases with maxillary sinusitis.

Most of the above investigations illustrate the correlation between x-ray findings and the presence of secretion inside the sinus in maxillary sinusitis. In order to demonstrate the retention of secretion inside the sinus in cases where the antral mucosa is thickened, more projections than the ordinary three or four are required in x-raying. Axelsson et al. (1970) in their investigation of 197 cases with maxillary sinusitis, reported secretion roentgenologically demonstrated inside the sinus in 24 % of cases with mucous membrane thickening, whereas this could be disclosed in 60 % through irrigation. When they added the fifth projection, the occipitomental with head horizontal and the affected side downwards, to the four standard projections, secretion was roentgenologically demonstrated in 88 % of the cases in which the puncture had been positive.

C. Ostial patency

Braune & Clasen (1877) reported changes of sinus pressure in their blowing experiment. Later Döderlein (1932) reported a decrease and increase of respiratory pressure inside the sinus in connection with empyema. Kerekes (1934) could not demonstrate these changes at the beginning of sinusitis, but they appeared at the recovery stage. After Proetz (1932) had observed that an open ostium transmits respiratory pressure changes from the nasal cavity into the sinus as unchanged, Flottes et al. (1960) stated that conclusions can be drawn about the ostial patency by comparing decrease and increase of respiratory pressures in the nasal cavity and the sinus.

Pressure measurements can be performed consecutively in the sinus and the nasal cavity or the nasopharynx. The disadvantage of these measurements is that the intensity of respiration continuously changes even in the same person. In order to eliminate this disadvantage simultaneous measurements have been used (Proetz, 1932, Drettner 1965b, Cottle 1968) in which decrease and increase of the respiratory pressure are measured simultaneously in the sinus and the nasal cavity or the nasopharynx. Drettner measured the pressures on both sides of the ostium by means of a trocar introduced into the sinus and a plastic catheter placed in the middle meatus on the same side. Cottle compared the pressure of the maxillary sinus with the pressure of the nasopharynx, which he measured through a nozzle in the nostril opposite to the investigated side. Kortekangas (1970, 1974) proposed recording of the pressure difference between the maxillary sinus and the nasopharynx as part of the ostial patency test. In all the other methods, the deviation of pressure from the ambient atmospheric pressure is first measured, after which the pressure curves of the sinus and nasal cavity or the nasopharynx are mutually compared.

In acute sinusitis there are respiratory pressure changes inside the sinus in 23.2 %. In only 8.4 %, however, are the pressure changes identical in the nasal cavity and the sinus (Drettner 1965c). On the basis of these observations, Drettner divided the ostia into patent, partially obstructed and obstructed. He regarded the ostium as patent if, during respiration, the decrease and increase of pressure in the plastic catheter and the trocar corresponded to each other. When the pressure changes inside the sinus were less pronounced than those in the nasal cavity, the ostium was called partially obstructed. If there was no antral decrease or increase of the respiratory pressure, he regarded the ostium as obstructed. A partial obstruction can, according to Drettner, be caused by the ostium itself, and also by the secretion that partially obstructs the ostium and/or the trocar. Rantanen & Kortekangas (1971) used the term partially patent for a partial obstruction; in a study comprising 30 maxillary sinusitis an ostial obstruction was reported in 56.6 % at diagnostic puncture, but at the end of treatment in only one case.

In addition to respiratory pressures, Drettner (1965b) also used pressures produced by sniffing and blowing when evaluating the ostial patency. He reported an ostial obstruction for sniff/blow pressures in acute maxillary sinusitis in 47.8 %, whereas sniffing and blowing opened an ostium obstructed for respiratory pressures in 25 % of the cases.

A valve phenomenon, earlier observed by Proetz (1932), Schmiecker (1932) and Kerekes (1934), was reported by Drettner (1965c) in an obstructed ostium in 13.3 % of the cases. Later the valve phenomenon was analysed by Drettner (1967

D. Ostial resistance

I measuring ostial resistance, Flottes et al. (1960) sed ir; they did not, ho ever recommend pressures exceeding the ambient atmospheric pressures with more than 200 mm H_2O because f the risk f air embolism. On the other hand, Soubeyrand (1964) pointed out that in subacute maxillary sinusitis the resistance is below that alue in only 8—12 % f cases. Consequently Drettner (1965a) and Zippel & Maier (1968) used fluid instead of air in their resistance measurements. Their methods f measuring ere similar.

Zippel & Meier stated that in healthy persons normal resistance aries from 100 to 250 mm H_2O In acut maxillary sinusitis resistance is normal in every other case, but elevated in the rest. Drettner pointed out that verage *resistance in sinusitis is 310 mm H_2O*. Where there is retention f antral secretion, resistance is 420 mm H_2O on verage, whereas it is 150 mm H_2O in cases without secretion. He reported that at recovery from sinusitis ostial resistance becomes normal.

Rantanen & Kortekangas (1971) showed that t diagnostic puncture ostial resistance in sinusitis is more than 135 mm H_2O in every third case and less than that in the rest. Where the ostium was patent or partially patent for respiration, no elevation in resistance was noted in this in estigation in 60 % f the cases. On the other hand, when the ostium was obstructed during respiration, resistance was less than 135 mm H O in 43.5 % f the cases.

investigators found retention of secretion inside the sinus in 0 % of cases with a *normal* x-ray finding. The corresponding results of McNeill (1963) were 83 %, 63 % and 20 % in an investigation of 150 cases with maxillary sinusitis.

Most of the above investigations illustrate the correlation between x-ray findings and the presence of secretion inside the sinus in maxillary sinusitis. *In order to demonstrate the relation of secretion inside the sinus in cases where the antral mucosa is thickened, more projections than the ordinary three or four are required in x-raying.* Axelsson et al. *(1970)* in their investigation of 19 cases with maxillary sinusitis, reported secretion roentgenologically demonstrated inside the sinus in 1 % *of cases* with mucous membrane thickening, whereas this could be disclosed *in 60 % through irrigation.* When they added the fifth *projection*, the occipitomental with head horizontal and the affected side downwards, to the four standard projections, secretion was roentgenologically demonstrated in 83 % of the cases in which the puncture had been positive.

C. Ostial patency

Braune & Clasen (1877) reported changes of *sinus pressure in their blowing experiment.* Later Döderlein (193) reported a decrease and increase of respiratory pressure inside the sinus in connection with empyema. Kerekes (1934) could not demonstrate these changes at the beginning of sinusitis, but they appeared at the recovery stage. After Proetz (1932) had observed that an open ostium transmits respiratory pressure changes from the nasal cavity into the sinus as unchanged, Flottes et al. (1960) stated that conclusions can be drawn about the ostial patency by comparing decrease and increase of respiratory pressures in the nasal cavity and the sinus.

Pressure measurements can be performed consecutively in the sinus and the nasal cavity or the nasopharynx. The disadvantage of these measurements is that the intensity of respiration continuously changes even in the same person. In order to eliminate this disadvantage simultaneous measurements have been used (Proetz, 193 , Drettner 1965b, Cottle 1968) in which decrease and increase of the respiratory pressure are measured simultaneously in the sinus and the nasal cavity or the nasopharynx. Drettner measured the pressures on both sides of the ostium by means of a trocar introduced into the sinus and a plastic catheter placed in the *middle meatus on the same side.* Cottle compared the pressure of the maxillary sinus with the pressure of the nasopharynx, which he measured through a nozzle in the nostril opposite to the investigated side. Kortekangas (1970, 1971) proposed recording of the pressure difference between the maxillary sinus and the nasopharynx as part of the ostial patency test. In all the other methods, the deviation of pressure from the ambient atmospheric pressure is first measured, after which the pressure curves of the sinus and nasal cavity or the nasopharynx are mutually compared.

In acute sinusitis there are respiratory pressure changes inside the sinus in ... in only 8.7 %, however, are the pressure changes identical in the nasal cavity and the sinus (Drettner 1965c). On the basis of these observations, Drettner divided the ostia into patent, partially obstructed and obstructed. He regarded the ostium as patent if, during respiration, the decrease and increase of pressure in the plastic catheter and the trocar corresponded to each other. When the pressure changes inside the sinus were less pronounced than those in the nasal cavity, the ostium was called partially obstructed. If there was no antral decrease or increase of the respiratory pressure, he regarded the ostium as obstructed. A partial obstruction can, according to Drettner, be caused by the ostium itself and also by the secretion that partially obstructs the ostium and/or the trocar. Rantanen & Kortekangas (1971) used the term partially patent for a partial obstruction. In a study comprising 36 maxillary sinusitis, an ostial obstruction was reported in 55.6 % at diagnostic puncture, but at the end of treatment in only one case.

In addition to respiratory pressures, Drettner (1965b) also used pressures produced by sniffing and blowing when evaluating the ostial patency. He reported an ostial obstruction for sniff/blow pressures in acute maxillary sinusitis in 4 .8 %, whereas sniffing and blowing opened an ostium obstructed for respiratory pressures in 3 % of the cases.

A valve phenomenon, earlier observed by Proetz (1932), Schmiedeker (1932) and Kerekes (1934), was reported by Drettner (1965c) in an obstructed ostium in 13. % of the cases. Later the valve phenomenon was analysed by Drettner (196).

V Methods

A. Clinical history and nasal state

Exact anamnestic information was obtained from all patients investigated. Attention was paid to earlier occurrences of maxillary sinusitis, as well as to the presence or absence of ache in the maxillary area, frequency and treatment of these and time elapsed from the last sinusitis. In addition to this, the relation between the present ache symptoms and ostial respiratory patency and resistance at diagnostic puncture, as well as duration of recovery were studied.

In nasal structure septal deformities and turbinal hypertrophies were observed. Cases with significant deformities were actually excluded from the investigation.

B. Bacteriology

In the sinusitis series bacteriologic samples, not controlled later on, were taken at diagnostic puncture. The sample was obtained through a trocar by sucking in 84 (71.2 %) cases and from irrigation dish, a so-called washed sample, in 34 (28.8 %) cases. The bacteria were studied by the usual bacteriological methods.

C. X-ray examination

X-ray examination of the sinuses was performed on the patients immediately before diagnostic puncture. It was not controlled later on. In the examination, anterior-posterior, lateral and occipitomental (Waters-Waldron) projections were used.

Thickness of the mucosa of the maxillary sinus was measured in the horizontal as well as the vertical direction. In both measurements the thicknesses of the mucosae were summed, and the result was compared with the respective diameter of the air space of the sinus.

The findings were defined as follows:

— *normal mucosa*, the mucosa could not be roentgenologically demonstrated or it was very thin
— *slightly thickened mucosa*: in both measurements the air space was wider in diameter than the summed thickness of the mucosae
— *markedly thickened mucosa*: in either one or both measurements the diameter of the air space was smaller than the summed thickness of the mucosae
— *fluid level* at the bottom of the sinus there appeared an opaque horizontal clouding bordering the air space and remaining horizontal irrespective of the projection
— *homogeneously clouded sinus*: no antral air space was demonstrated.

D. Ostial patency tests

1. Procedure

Before investigation the patient cleared his nose by blowing. After this nasopharyngeal and antral pressure changes during quiet nasal respiration were measured using the consecutive measuring technique, as well as antral pressure changes during sniffing and blowing, the so-called sniff/blow pressures. When nasopharyngeal and antral pressure changes were compared, only the peak values of the pressure decrease and increase were taken into consideration.

The investigation procedure was as follows (Fig. 1):

Step 1. The sinus was punctured under local anaesthesia (lidocaine 4 %) by introducing a Lichtwitz trocar (inner diameter 1.5 mm) through the inferior meatus.

Step 2. Respiratory pressure variations in the nasopharynx were recorded during quiet respiration using the anterior rhinomanometric technique (Fig. 1, I).

Step 3. The corresponding respiratory antral pressure variations were recorded through the Lichtwitz trocar by connecting it air-tightly to a manometer. The opposite nostril was closed with a finger (Fig. 1, II).

IV Material

The **sinusitis** series consisted of 86 patients with acute untreated maxillary sinusitis (Table 2). Investigation of ostial function and treatment of sinusitis were performed at the Department of Otolaryngology of the University Central Hospital of Turku during the years 1970—1971 simultaneously with the investigation of the control series. In 118 sinuses antral infection was apparent: in 54 patients this was unilateral, in 32 patients bilateral. There were 59 females (68.6 %) and 27 (31.4 %) males in the series. Their age varied from 12 to 77 years, mean age being 33.7 years, 32.7 years for females and 35.0 years for males.

Table 2. *Sinusitis series.*

	Unilateral testing	Bilateral testing	N of persons	N of sinuses
Female	34	25	59	84
Male	20	7	27	34
Total	54	32	86	118

The patients in the sinusitis series met the following requirements:
- they had symptoms of acute rhinitis
- the x ray showed changes typical for acute maxillary sinusitis
- at diagnostic puncture retention of secretion was found.

The effect of drugs on sinusitis was not dealt with in this investigation. The treatment was, as can be seen from the methods, irrigation of the diseased sinus once a week. All patients were given the same nasal drops, xylometazolin chlorid. 0.1 % and 47 patients (60 sinuses) also received oral antibiotics, penicillin or tetracyclin, for a week.

Table 3. *Control series.*

	Unilateral testing	Bilateral testing	N of persons	N of sinuses
Female	13	8	21	29
Male	6	8	14	22
Total	19	16	35	51

The **control** series consisted of 35 patients at the same clinic, all of whom had agreed to the investigation of ostial function (Table 3). There were 21 (60 %) females and 14 (40 %) males. Altogether 51 sinuses were investigated. A unilateral investigation was performed for 19 patients and a bilateral investigation for 16. The age of the patients varied from 17 to 76 years, mean age being 37.5 years, 38.6 years for females and 35.3 years for males.

The patients in the control series met the following requirements:
- no active respiratory infection was observed
- no subjective nasal symptoms were reported
- at diagnostic puncture no retention of antral secretion was found.

F g. 2.
Comparison f nasopharyngeal and antral pressure variation in different types f ostial patency Calibration mark equals 20 mm of water.

St tist l evaluation.

A statistical comparison of the pressure variation was made by observing the means of five successive peak alues of the inspiratory pressure decrease and the corresponding expiratory increase. Student t-test as employed in this analysis. The nasopharyngeal and antral pressure ariation was considered to be equal when $p > 0.01$.

b. E aluation f sniff/blow test

I determining the ti l p tran e, term hich in the present study refers to the patency f the ostium in sniffing and blowing, the peak values of the pressure decrease and increase during sniffing and blo ing were recorded. When the antral pressure change as more than 00 mm H O the penetrance was regarded normal. If the pressure change as 60—21 or 20—1 mm H_2O the penetrance as termed *d minished.* I addition to these, there were cases in which the sniff/blow pressures did not produ any antral pressure change, there was no *penetrance*

Antral p e t r to original level aft sniffing and blo ing was estimated as follow (Fig. 3)

— *normal return* antral pressure occurring on sniffing or blo ing returned to original level in $\leq$ 0.5 sec.
— *delayed ret rn* antral pressure returned to original level after sniffing or blowing, but the return took longer than 0.5 sec.
— *al ph nomenon* antral pressure did not return to riginal level after sniffing or blowing.

The iff/bl w ff t on ostial respiratory patency was evaluated as follo s (Fig. 4):

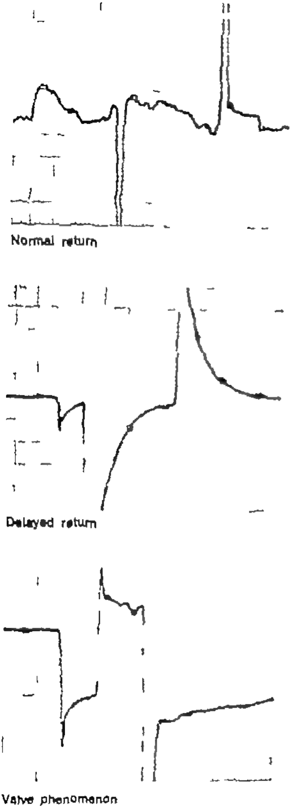

Fig. 3
Antral pressure return to original level after sniffing and blowing. Calibration is the same as in Figure –.

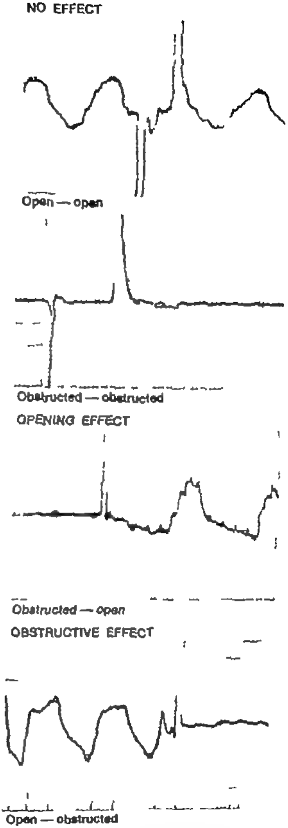

Fig. 4
Effect of sniff/blow pressures on the ostial respiratory pattern. Calibration is the same as in Figure 2.

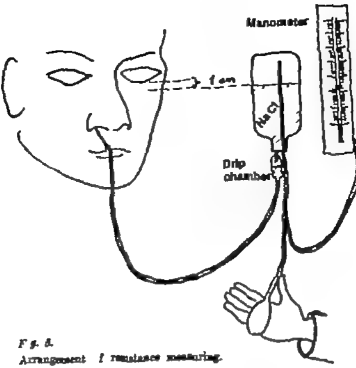

Fig. 5.
Arrangement of resistance measuring.

If antral respiratory variations remained equal to those before sniffing or blowing, the result was called *no-effect*. An *opening effect* means that an obstructed ostium became open or partially open. Another possibility was that a partially open ostium became open. An *obstructive effect* means that an open ostium became only partially open or obstructed, also that a partially open ostium became obstructed.

B. Ostial resistance measurements

1. *Procedure*

Measurements were performed before and after irrigation of the sinus. Before irrigation, measurement was taken of the smallest overpressure in the infusion bottle (saline, 0.9 %) needed to make the irrigation fluid and possible secretion flow through the ostium from the sinus into the nasal canal, i.e. resistance before irrigation. The same measuring was repeated after irrigation, i.e. resistance after irrigation.

At the beginning of resistance measurement, the infusion bottle was fixed so that the fluid level was on the same level as the ostium, about 1 cm beneath the inferior margin of the orbita. The bottle was connected with a Lichtwitz trocar by tubing (Fig. 5). The pressure inside the bottle was elevated with a hand-pump if necessary. Pressure values were read from a mercury manometer at the moment the fluid began to flow in the drip-chamber.

2. *Evaluation of results*

In evaluating resistance, the findings were grouped according to pressure values as follows: 0—5 mm Hg, 6—50 mm Hg and higher than 50 mm Hg. When the pressure value was 0—5 mm Hg, the resistance was regarded normal. If the value was 6—50 mm Hg, the resistance was regarded as *slightly elevated*, and a value more than 50 mm Hg *markedly elevated*.

For patients in the s i n u s i t i s series, the ostial patency tests and resistance measurements were repeated weekly until recovery. Observations were made at diagnostic puncture and at the end of treatment, when the sinus was free of secretion and the infection cured. Observations not included in the above were considered to have been made during treatment.

The patients in the c o n t r o l series were examined once.

In comparing results the Chi square test was used. In all cases the difference was called significant if $p < 0.05$.

VI Model experiments

A. Equipment and procedure

The aim of the model experiments was to obtain additional information about certain details of the ostial patency tests.

A model made of transparent plastic was used. It consisted of a nose component and a sinus component. The sinus component had three openings, two on the side of the nasal component, one on the lateral side. The posterior opening facing the nose component was filled with a rubber plug through which a Lichtwitz trocar (inner diameter 1.7 mm) was inserted in order to measure antral pressures. The anterior opening corresponding to the ostial canal was first closed air-tightly with wax. The model ostia were made by perforating the wax with needles, the thickness of which varied from 0.05 to 4.5 mm. The length of the model ostia in the experiments referred to below was 1 mm, but even considerably longer model ostial canals gave very similar results. The only use of the lateral opening was cleaning of the ostial canal and the sinus component.

The tube of the respirator (Engström Modell 200) was air-tightly connected to the posterior end of the nose component. The diameter of the circular anterior opening was 4.0 mm. The nose component and sinus component were air-tightly connected.

The pressure measurements of the nose component were performed through the Lichtwitz trocar (Fig. 6, I). The peak values of the inspiratory/expiratory pressures were arranged to be 12/8, 24/16 and 48/32 mm H_2O in the nose component of the model. After the pressure changes in the nose component of the model had been stabilized the pressures inside the sinus component were measured through the Lichtwitz trocar (Fig. 6, II). By varying the size of the ostia the diameter of the smallest ostium was defined at which the peak values of the respiratory pressure change in the nose component corresponded to those inside the sinus component. The results were recorded and registered in the same way as in the antral study.

Sniffing and blowing were performed by the same person through the model, with one of the nostrils closed (Fig. 6, III). An attempt was made to always perform sniffing and blowing in the same way.

Two types of "secretion" were used in the model experiments: saline 0.9 % and mucus obtained by mixing and homogenizing nasal mucus from a number of healthy persons.

All measurements were repeated twice and results were identical. Where they were not identical, a fault in the equipment was found.

B. Test results with model

Decrease and increase of the respiratory pressures were transmitted from the nose component through the ostium into the sinus component as unchanged if the ostium was free of "secretion" and its diameter was $\geq$ 0.4 mm and when the inspiratory/expiratory pressure change in the nose component was 12/8 mm H_2O (Table 4). If this pressure change was 24/16 or 48/32 mm H_2O the diameter of the ostium had to be at least 0.5 mm for the pressure changes of the nose and sinus components to be identical. If the ostium was occluded by saline, pressure changes in the nose and sinus components corresponded if the ostial diameter was 1.5 mm, when the respiratory

Table 4. *The smallest ostial diameter in mm for pressure changes in the nose and sinus components of the model being equal*

Ostium	Inspiratory/expiratory peak pressure, mm H_2O 12/8	24/16	48/32
Ostium free of secretion	0.4	0.5	0.5
Saline in the ostium			
before suction	1.5	1.0	0.8
after suction	0.4	0.5	0.5
Mucus in the ostium			
before suction	—	—	—
after suction	0.4	0.6	0.6

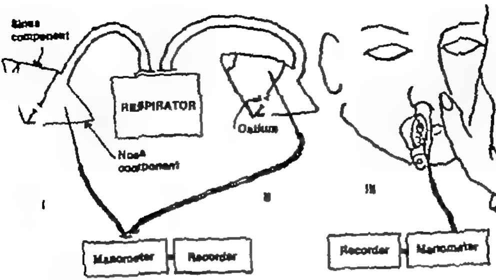

Fig. 6.
Arrangement of model recordings.

I. Recording of respiratory pressure in the nose component
II. Recording of respiratory pressures in the sinus component
III. Recording of sniff/blow pressures in the sinus component

pressure change was 12/8 mm H_2O. The diameters had to be 1.0 mm or 0.3 mm respectively when the pressure changes were 24/16 or 48/32 mm H_2O.

If the ostium was occluded by mucus, no regular respiratory pressure changes could be recorded inside the sinus component, even when the ostial diameter was 4.5 mm and respiratory pressure changes were 48/32 mm H_2O. When saline was sucked from the ostium through the Lichtwitz trocar, the patency recordings after suction corresponded to those obtained with an ostium free of secretion. Patency recordings were also similar when mucus was sucked from the ostium and respiratory pressure changes were 12/8 mm H_2O. If pressure changes were 24/16 or 48/32 mm H_2O, the pressure changes of the nose and sinus components corresponded as long as the ostial diameter was at least 6.0 mm.

The pressure change inside the sinus component produced by sniffing and blowing was more than 60 mm H_2O if the ostial diameter was $\gtrless 0.2$ mm, when the ostium was free of secretion or occluded with saline. If there was mucus in the ostium, the pressure change recorded inside the sinus component greatly depended on whether the mucus was mainly on the side of the sinus or on that of the nasal canal. If the mucus was mainly inside the sinus, a pressure decrease of more than 60 mm H_2O was produced inside the sinus on sniffing with the ostial diameter $\geqq 3.5$ mm. On blowing, a corresponding pressure increase was produced, with the diameter $\geqq 0.2$ mm. If the mucus was mainly on the side of the nasal canal, a pressure decrease of more than 60 mm H_2O was produced inside the sinus on sniffing, with the ostial diameter $\geqq 0.$ mm, and on blowing, a corresponding pressure increase was produced when the diameter was $\lesssim 3.0$ mm.

When the ostium was free of secretion or occluded with saline, the pressure changes inside the sinus component after sniffing and blowing normally returned to the original level, if the ostial diameter was $\gtrless 0.5$ mm. *If the diameter* was smaller the return was delayed. The return was also delayed when there was mucus in the ostium. In this case an air bubble, which slowly withdrew into the ostium, was produced on sniffing at the *opening of the* ostium on the

VI Model experiments

Ostium	Inspiratory/expiratory peak pressures in mm H_2O 12/8	24/16	48/32
Ostium free of secretion	0.4	0.5	0.5
Saline in the ostium			
before suction	1.5	1.0	0.8
after suction	0.4	0.5	0.5
Mucus in the ostium			
before suction	—	—	—
after suction	0.4	0.6	0.6

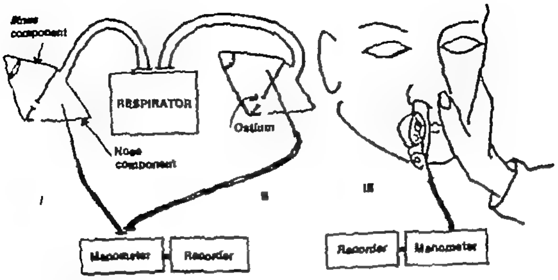

Fig. 6.
Arrangement f model recordings.

I. Recording of respiratory pressure in the nose component
II. Recording of respiratory pressures in the sinus component
III. Recording f sniff/blow pressures in the sinus component

pressure change was 14/8 mm H_2O. The diameters had to be 1.0 mm or 0.8 mm respectively when the pressure changes were 24/16 or 48/32 mm H_2O.

If the ostium was occluded by mucus, no regular respiratory pressure changes could be recorded inside the sinus component, even when the ostial diameter as 1.5 mm and respiratory pressure changes ere 48/32 mm H_2O. When saline was sucked from the ostium through the Lichtwitz trocar the patency recordings after suction corresponded to those obtained with an ostium free f secretion. Patency recordings ere also similar when mucus was sucked from the ostium and respiratory pressure changes ere 12/8 mm H_2O. If pressure changes were 24/16 or 48/32 mm H_2O the pressure changes f the nose and sinus components corresponded as long as the ostial diameter as at least 0.5 mm.

The pressure change inside the sinus component produced by n ffing and blow g as more than 60 mm H_2O if the ostial diameter was $\geq$ 0.2 mm, when the ostium was free of secretion or occluded with saline. If there as mucus in the ostium, the pressure change recorded inside the sinus component greatly depended on whether the mucus was mainly on the side f the sinus or on that of the nasal canal. If the mucus was mainly inside the sinus, pressure decrease f more than 60 mm H_2O was produced inside the sinus on sniffing with the ostial diameter $\geq$ 3.5 mm on blo ing, corresponding pressure increase was produced, with the diameter $\geq$ 0.2 mm. If the mucus was mainly on the side of the nasal canal, pressure decrease of more than 60 mm H_2O was produced inside the sinus on sniffing, with the ostial diameter $\geq$ 0.2 mm and on blowing, a corresponding pressure increase w produced when the diameter was $\geq$ 3.0 mm.

When the ostium was free f secretion or occluded with saline, the pressure changes inside the sinus component after sniffing and blowing normally returned to the original level, if the ostial diameter was $\geq$ 0.5 mm. If the diameter as smaller, the return was delayed. The return was also delayed when there was mucus in the ostium. In this case an air bubble, which slowly ithdrew into the ostium, was produced on sniffing at the pening f the ostium on the

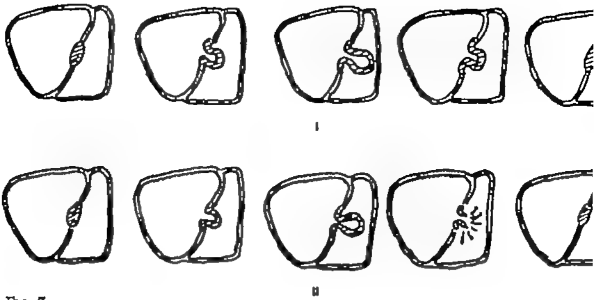

Fig 7
Changes in mucus at the ostium of the model during sniffing

I. Delayed return
II. Valve phenomenon

side of the nasal canal (Fig 7 I) On blowing a similar bubble appeared on the side of the sinus. The size of the bubble depended on the amount of mucus as well as on the intensity of sniffing and blowing. The ostial diameter appeared to have no effect on the frequency of delayed return.

The valve phenomenon did not occur if the ostium was free of "secretion" or occluded with saline. If there was mucus in the ostium, the phenomenon usually occurred, depending on the amount of mucus and the intensity of sniffing and blowing as well as on the size of the ostium. It was observed through the wall of the model that a valve appeared when the bubble produced

on sniffing or blowing burst, and at once ostium again became occluded (Fig 7 II) this case, the pressure remaining inside sinus after sniffing was less than one at phere and after blowing greater than one mosphere. When sniff/blow pressures of o intensity were used, and when the amoun mucus in the ostium was the same, delayed turn and the valve phenomenon were freque observed, if the ostial diameter was ≤ 3.0 If the diameter was larger than this, the mu did not occlude the ostium so frequently it remained open. If the valve was accompa by the delayed return of the sinus press this was due to an air leak in the appara

VII Results

A. Clinical history and nasal state

I the sinu iti series 39.8 % ($^{47}/_{118}$) of the patients had earlier contracted maxillary sinusitis, in 20 cases three times or more. In 8.5 % (/) 1—3 months had elapsed from the last sinusitis, in the other cases more than three months. The infection had been treated in 40 cases ith series f puncture and drugs. In se en cases, only drugs had been given follo ing the diagnostic puncture.

Earlier ache had occurred once or more than once in 18.6 % ($^{22}/_{118}$) In 15 cases, the symptom had not been treated, and in seven cases drugs had been prescribed. One patient had vasomotor rhinitis. On this occasion, ache was localized in the sinus area in 60.2 % ($^{71}/_{118}$) Maxillary sinusitis was accompanied by acute frontal sinusitis in 3.4 % (/118)

The size f the nasal cavity was normal in 77.1 % ($^{91}/_{118}$) Inferior turbinate hypertrophy as observed in 22.9 % ($^{27}/_{118}$) but only in 5.1 % (/118) did it cause partial posterior obstruction of the nasal cavity

In the t l series, 23.5 % ($^{30}/_{n}$) of the patients had earlier contracted maxillary sinusitis. In all cases, over three months had passed since the last sinusitis. In seven cases, treatment had consisted f series f punctures and drugs in th cases, only drugs had been given follo ing the diagnostic puncture. Two patients f the control series reported that they had earlier experienced ache in the maxillary area. Possible maxillary sinusitis was not, how ever diagnosed. In the latter tw cases, no treatment had been gi en. N vasomotor rhinitis as f und in the patients investigated. N obstructiv septum deformities were detected. The turbinates were normal in 92.2 % ($^{47}/_{51}$) Inferior turbinate hypertrophy occurred in 7.8 % (/51) but this did not obstruct the nasal canal.

B. Bacteriological findings

Bacteria ere isolated from the sinus secretion in 68.6 % ($^{81}/_{118}$) Respiratory pathogenic bacteria occurred in 58.4 % ($^{69}/_{118}$) (*Table 5*) Diplococcus pneumoniae was the most common bacterium, being found in 37.3 % ($^{44}/_{118}$) Haemophilus influenzae was found in 22.0 % ($^{26}/_{118}$) The secretion was sterile in 31.4 % ($^{37}/_{118}$)

C. X ray findings

There ere changes in all the sinuses f the i iti series (Table 6) The thickening of the mucosa was slight in 23.7 % ($^{28}/_{118}$) and marked in 21. % ($^{25}/_{118}$) A fluid level as observed in 32.2 % ($^{38}/_{118}$) and the sinus was homogeneously clouded in 22.9 % ($^{27}/_{118}$)

A normal mucosa occurred in 64.7 % ($^{33}/_{51}$) in the t l series, and slight thickening of the mucosa in 33.3 % (51) The sinus as homo neously cl uded in .0 (51)

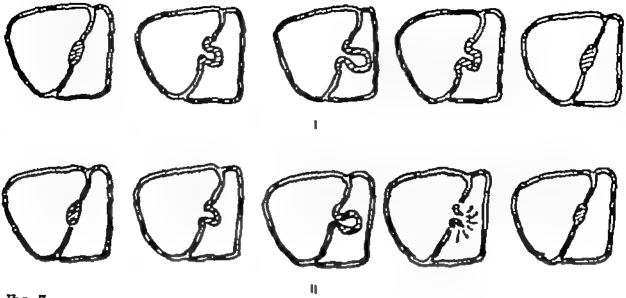

Fig 7
Changes in mucus at the ostium of the model during sniffing

I. Delayed return
II Valve phenomenon

side of the nasal canal (Fig 7 I) On blowing a similar bubble appeared on the side of the sinus. The size of the bubble depended on the amount of mucus as well as on the intensity of sniffing and blowing The ostial diameter appeared to have no effect on the frequency of delayed return.

The valve phenomenon did not occur if the ostium was free of secretion or occluded with saline. If there was mucus in the ostium, the phenomenon usually occurred, depending on the amount of mucus and the intensity of sniffing and blowing as well as on the size of the ostium. It was observed through the wall of the model that a valve appeared when the bubble produced on sniffing or blowing burst and at once the ostium again became occluded (Fig. 7 II) In this case, the pressure remaining inside the sinus after sniffing was less than one atmosphere and after blowing greater than one at mosphere. When sniff/blow pressures of equal intensity were used, and when the amount of mucus in the ostium was the same delayed return and the valve phenomenon were frequently observed, if the ostial diameter was ≤ 3.0 mm. If the diameter was larger than this, the mucus did not occlude the ostium so frequently and it remained open. If the valve was accompanied by the delayed return of the sinus pressure, this was due to an air leak in the apparatus.

both the inspiratory and expiratory pressures were transmitted in the same way through the ostium from the nose into the sinus.

In ele en cases, both the inspiratory and ex piratory v rage pressures are significantly higher inside the sinus than in the nasopharynx, the ostium being of course open in these cases (Table 9). In the statistical comparison of average pressures of the nasopharynx and sinus, no significant difference was observed during inspiration in 11.9 % ($^{14}/_{118}$) and during ex piration in 22.6 % ($^{19}/_{84}$) when the ostium was partially open. In all other cases, the difference was significant.

In the c n t r o l series, the ostium was pen natively in 58.8 % ($^{30}/_{51}$) postfunctionally in 64. % ($^{33}/_{51}$) and postirrigationally in 70.6 % ($^{36}/_{51}$). With all the three phases f each examination included, the ostium was open in 80.2 % ($^{41}/_{51}$).

The statistical comparison of average pressure hanges f the sinus and nasopharynx revealed that the inspiratory pressure decrease in the nasopharynx was transmitted into the sinus as equal or as significantly decreased nati ely in 02.7 % ($^{37}/_{51}$) postfunctionally in 64.7 % ($^{33}/_{51}$) and postirrigationally in 66.7 % ($^{34}/_{51}$) corresponding values for the expiratory pressure increase were 72.5 % ($^{37}/_{51}$) 78.4 % ($^{40}/_{51}$) and 58.8 % ($^{30}/_{51}$). No difference was recorded between inspiration and expiration in the mutual comparison f the results obtained at postfunctional examination.

D. Respiratory pressure variations in the nasopharynx

The nasopharyngeal pressure variation, recorded for reference purposes, was measured by anterior rhinomanometry after the trocar had already been inserted. For the sinusitis series, an average inspiratory pressure decrease of 14.80 mm H_2O and an expiratory pressure increase of 1[illegible].50 mm H_2O were recorded. The corresponding figures for the control series were 14.[illegible] mm H_2O and 12.21 mm H_2O.

E. Results of ostial patency tests

1. Respiratory patency

a. Effect of suction and irrigation on ostial respiratory patency

In the sinusitis series, the ostium was open natively in 24.2 % ($^{[illegible]}/_{[illegible]}$) postsuctionally in 33.4 % ($^{[illegible]}/_{[illegible]}$) and postirrigationally in 29.1 % ($/_{[illegible]}$) (Table 7). Suction had no significant effect on ostial patency at diagnostic puncture or at the end of treatment. When the results obtained during treatment of sinusitis were mutually compared, it was noted that suction affected the ostial patency: the ostium was open at postsuctional examination significantly more often than at native examination ($\chi^2 = 7.73$, df = 2). When the most normal one of the three observation results of each examination was chosen as the finding, the ostium was open in 43.3 % (/[illegible]) partially open in 23.9 % ($^{[illegible]}/_{[illegible]}$) and obstructed in 32.8 % ($^{[illegible]}/_{[illegible]}$) of the sinusitis series. An open ostium occurred here significantly even more often than at the postsuctional examination, which usually gives the result closest to normal (χ^2 = [illegible].71, df = 1).

When the average pressure changes of the nasopharynx and sinus were statistically compared, the inspiratory antral pressures were equal to, or had decreased significantly more than those of the nasopharynx natively in [illegible].8 % ($^{[illegible]}/_{[illegible]}$) postsuctionally in 35.6 % ($^{[illegible]}/_{[illegible]}$) and postirrigationally in 20.4 % ($^{[illegible]}/_{[illegible]}$); the corresponding values of the expiratory pressure increase were [illegible].9 % ($^{[illegible]}/_{[illegible]}$) 33.4 % ($^{[illegible]}/_{[illegible]}$) and 29.4 % ($^{[illegible]}/_{[illegible]}$) (Table 8). Also in the statistical comparisons of average pressure changes of the sinus and the nasopharynx the ostium was open for inspiratory pressures significantly more often at the postsuctional examination than at the native examination (χ^2 = 6.[illegible]6, df = 1) during the treatment of sinusitis, but not at diagnostic puncture or at the end of treatment.

During expiration this difference was not observed. According to the postsuctional results

in 23.0 % ([illegible]) and obstructed in 32.8 % ([illegible]) of the sinusitis series. An open ostium occurred here significantly even more often than at the postsuctional examination, which usually gives the result closest to normal (χ^2 = 2.71 df = 1)

When the average pressure changes of *the nasopharynx and sinus were statistically compared*, the inspiratory antral pressures were equal to or had decreased significantly more than those of the nasopharynx natively in 23.8 % ([illegible]) postsuctionally in 35.6 % ([illegible]) and postirrigationally in 20 4 % ([illegible]) the corresponding values of the expiratory pressure increase were 23.9 % ([illegible]) 33.4 % ([illegible]) and 20 4 % ([illegible]) (Table 8) Also in the statistical comparisons of average pressure changes of the sinus and the nasopharynx the ostium was open for inspiratory pressures *significantly more often at the postsuctional* examination than at the native examination (χ^2 = 6.70, df = 1) during the treatment *of sinusitis, but not at diagnostic puncture* or at the end of treatment.

During expiration this difference was not observed. According to the postsuctional results

In sinusitis, no significant alterations took place in ostial respiratory patency until the sinus was free of secretion.

At diagnostic puncture, the ostium was found to be obstructed during respiration in 56.8 % and at the end of treatment in 12.7 % of cases.

2. Sniff/blow test

a. Ostial sniff/blow penetrance

In the sinusitis series, the ostial penetrance on sniffing at diagnostic puncture was normal natively in 29.6 % ($^{33}/_{111}$) both postsuctionally and postirrigationally in 38.4 % ($^{43}/_{111}$) (Table 11). The corresponding penetrance on blowing was normal natively in 15 % ($^{29}/_{108}$), postsuctionally in 33.6 % ($^{42}/_{108}$) and postirrigationally in 39.8 % ($/_{118}$). In all other cases, either the sniff/blow penetrance was diminished or there was no penetrance.

The sniff/blow penetrance during and at the end of treatment is presented in Table 11. The table shows that postirrigationally the sniff/blow penetrance was most frequently normal at diagnostic puncture and during treatment, but postsuctionally at the end of treatment. Comparison of ostial penetrance recordings obtained at the native and postirrigational examination indicate that suction and irrigation significantly improved the penetrance during treatment of sinusitis ($\chi^2 = 12.31$, df $= 3$).

In the control series the penetrance on sniffing was normal in all cases, both at the native and postsuctional examination. Postirrigationally the penetrance was diminished, 60—21 mm H O in 3.9 % ($/_{51}$) and normal in the rest. The penetrance on blowing was normal at the native and postsuctional examination in 96.1 % ($^{49}/_{51}$). In one case at the native examination there was no penetrance, in the rest the penetrance was diminished.

b. Return of sniff/blow pressures

In the sinusitis series, the return of antral pressure was normal after sniffing in 51.4 % ($^{113}/_{220}$) and after blowing in 40.8 %

b Alterations of patency

The ostium was obstructed in the s i n u s i t i s series significantly more often both at diagnostic puncture ($\chi^2 = 47.28$, df = 2) and during treatment ($\chi^2 = 43.05$, df = 2) than in the c o n t r o l series, when the ostial postunctional patency was evaluated clinically (Table 7). At the end of treatment there was no difference between the ostial patency of these series. When the average inspiratory pressure decreases of the nasopharynx and the sinus were statistically evaluated, a corresponding difference between the series was observed at diagnostic puncture ($\chi^2 = 26.60$, df = 1) and during treatment ($\chi^2 = 20.52$, df = 1) but not at the end of treatment, using results obtained at the postunctional examination (Table 8). When expiratory pressure increases were compared between the series, the difference was significant at diagnostic puncture during and at the end of treatment ($\chi^2 = 45.25$, 43.5 and 7.29, df = 1).

When alterations in the ostial patency were observed weekly, the patency was similar to that recorded at diagnostic puncture as long as there was antral retention of secretion (Table 10). If sinusitis was cured within the first two weeks, ostial patency was significantly better at the end of treatment than at diagnostic puncture ($\chi^2 = 46.20$ and 17.13, df = 2). In cases in which the sinusitis was cured within the first week, the ostial patency was similar to that of the control series, but in cases cured within the second week, the difference between series was significant ($\chi^2 = 9.14$, df = 2). If the treatment was continued, the ostial patency *differed significantly* from the patency of the control series during the first three weeks of treatment ($\chi^2 = 39.68$, 29.99 and ...0, df =).

At successive examinations, no change in the patency of the same ostium was observed in 49.8 % (/...). An obstructed ostium became open or partially open, or a partially open ostium became open in 30.9 % (/...). An open ostium became partially open or obstructed, or a partially open ostium became obstructed in 11.5 % (/...). There were 37 cases in which a previously obstructed ostium was observed to be open at the following examination: this occurred after the first week of treatment in 16 cases and after the second week in 11 cases. In all these cases sinusitis had been cured. Of the 26 ostia open at diagnostic puncture three became obstructed during treatment. In two cases, the obstruction was present at all three phases of the examination; in the third case the ostium was open at the postirrigational examination.

Comment. Ostial respiratory patency should be examined after trials to eliminate the disturbing influence of secretion in the tubings between the tip of the trocar and the manometer or in the ostial canal itself by suction through the trocar.

Table 10. *Weekly alterations in ostial respiratory patency. Patency determined at postunctional examination*

Patency	At diagnostic puncture	After 1 week	After 2 weeks	After 3 weeks	After 4 weeks	After 5 weeks	% of sinuses
Open	26						20
Partially open	25						[illegible]
Obstructed	67						67
		During treatment					
Open		13	3	4			20
Partially open		13	6	1			10
Obstructed		34	10	5			51
		At end of treatment					
Open		35	1	5	1	1	63
Partially open		20	12	3	4	1	40
Obstructed		9	0		3		15
No. of sinuses	118	119	00	18	10	[illegible]	[illegible]

In sinusitis, no significant alterations took place in ostial respiratory patency until the sinus was free of secretion.

At diagnostic puncture, the ostium was found to be obstructed during respiration in 56.8 % and at the end of treatment in 1..7 % of cases.

2. Sniff/blow test

a. Ostial sniff/blow penetrance

In the sinusitis series, the ostial penetrance on sniffing at diagnostic puncture was normal natively in 28.0 % (³³/₁₁₈) both postsuctionally and postirrigationally in 36.4 % (⁴³/₁₁₈) (Table 11). The corresponding penetrance on blowing was normal natively in 24.0 % (²⁹/₁₁₈) postsuctionally in 35.6 % (⁴²/₁₁₈) and postirrigationally in 39.8 % (/₁₁₈). In all other cases, either the sniff/blow penetrance was diminished or there was no penetrance.

The sniff/blow penetrance during and at the end of treatment is presented in Table 11. The table shows that postirrigationally the sniff/blow penetrance was most frequently normal at diagnostic puncture and during treatment, but postsuctionally at the end of treatment. Comparison of ostial penetrance recordings obtained at the native and postirrigational examination indicate that suction and irrigation significantly improved the penetrance during treatment of sinusitis ($\chi^2 = 12.31$, df = 3)

In the control series the penetrance on sniffing was normal in all cases, both at the native and postsuctional examination. Postirrigationally the penetrance was diminished, 60—21 mm H_2O in 3.9 % (/₅₁) and normal in the rest. The penetrance on blowing was normal at the native and postsuctional examination in 96.1 % (⁴⁹/₅₁). In one case at the native examination there was no penetrance, in the rest the penetrance was diminished.

b. Return of sniff/blow pressures

In the sinusitis series, the return of antral pressure was normal after sniffing in 51.4 % (¹⁸²/₃₅₄) and after blowing in 49.8 %

T ble 11. *The penetrance of sniff/blow pressures at the maxillary sinus in the three phases of each examination. Pressure in mm H_2O. Figures give the numbers of sinuses examined.*

([illegible]) (Table 12). It was delayed after sniffing in 13.6 % ([illegible]) and after blowing in 13.7 % ([illegible]). The ostium acted as a valve on sniffing in 14.9 % ([illegible]) and on blowing in 1[illegible].5 % ([illegible]). In comparing the different phases of the same examination, the valve was observed natively in 12.0 % ([illegible]) *on sniffing and in 9.5 % ([illegible]) on blowing*. Postsuctionally the valve was almost as common, but postirrigationally the frequency was 2[illegible].7 % ([illegible]) on sniffing and 18.4 % ([illegible]) on blowing.

At diagnostic puncture the valve on sniffing was significantly more frequent after irrigation than at the native examination ($\chi^2 = 9.79$, df $= 2$). The situation was the same at the end of treatment both on sniffing ($\chi^2 = 10.83$, df $= 2$) and on blowing ($\chi^2 = 9.0$[illegible], df $= 2$) comparing frequencies of postsuctional and postirrigational examinations. There was no difference between sniffing and blowing as regards the pressure return after irrigation.

In the control series, the return of pressure was normal at the native examination after sniffing in 98.1 % ([illegible]) and after blowing in 98.0 % ([illegible]). The return was normal after sniffing and blowing in 98.0 % ([illegible]) at the postsuctional examination and in 84.3 % ([illegible]) at the postirrigational examination. In all the phases of each examination the return was delayed in 2.0 % ([illegible]) after sniffing and in three cases after blowing. Two of these three occurred after irrigation and one after suction. The ostium acted as a valve natively in [illegible]0 % ([illegible]) *and postirrigationally in 13.*[illegible] ([illegible]) on sniffing. After blowing the valve was seen only after irrigation in 11.8 % ([illegible]).

c. Effect of sniffing and blowing on ostial patency

In the *sinusitis* series, either an opening or obstructive effect on ostial patency occurred on sniffing in 8.6 % ([illegible]) and on blowing in 3.8 % ([illegible]) (Table 13). The difference between the effects of sniffing and blowing was significant when postirrigational results were mutually compared ($\chi^2 = 1$[illegible]$.40$, df $= 1$).

The obstructive effect on sniffing occurred at the postsuctional examination significantly more often than at native examination ($\chi^2 = 11.06$, df $= 1$) or at the postirrigational examination ($\chi^2 = 6.58$, df $= 1$). Blowing did not have this effect.

Table 13. *The effect of sniffing and blowing on the ostial respiratory patency. Figures refer to numbers of sinuses.*

	Effect of sniffing				Effect of blowing			
	No effect	Opening effect	Obstructive effect	No antral pressure change	No effect	Opening effect	Obstructive effect	No antral pressure change
Sinusitis series								
Native	226	23	4	73	226	4		57
Postinctional	223	11	19	73	229	5	8	84
Postirrigational	235	20	7	64	249	8	5	64
Control series (diagnostic puncture)								
Native	51				50			1
Postinctional	51				51			
Postirrigational	50	1			50	1		

In the control series, both sniffing and blowing altered the ostial patency only once. In both cases, an obstructed ostium became open.

Comment. The ostial sniff/blow penetrance was most often normal after the secretion had been removed from the sinus and the trocar by means of irrigation and suction. The postirrigational penetrance was normal at diagnostic puncture in 38.1 % and at the end of sinusitis treatment in 82.9 %; the corresponding observation for the control series was 95.1 % of cases.

The antral pressure return after sniffing and blowing was normal most often postinctionally. At diagnostic puncture, the return was normal in 33.5 % and at the end of treatment in 84.7 %. In other cases of sinusitis, either delayed return or valve phenomenon occurred, the latter being significantly more frequent postirrigationally. In the control series, the return was normal in 98.0 % of cases.

Sniffing and blowing had an effect on ostial patency in 6.2 % of cases in the sinusitis and in 0.7 % in the control series.

F. Ostial resistance

1. Resistance before irrigation

In the sinusitis series, resistance was normal, 0—5 mm Hg, in 53.1 % ($^{173}/_{326}$), slightly elevated, 6—50 mm Hg in 28.8 % ($^{94}/_{326}$) and markedly elevated, more than 50 mm Hg in 18.1 % (/326) (Table 14). Resistance was normal before irrigation at diagnostic puncture in 28.0 % ($^{33}/_{118}$), during treatment in 47.8 % ($^{43}/_{90}$) and at the end of treatment in 82.2 % (/118).

Table 14. *The distribution of sinuses in three groups (0—5, 6—50, > 50 mm Hg) of ostial resistance.*

	Before irrigation 0—5	6—50	> 50	After irrigation 0—5	6—50	> 50	No. of sinuses
Sinusitis series							
At diagnostic puncture	33	52	33	68	68	2	/118
During treatment	43	29	18	62	28		/90
At end of treatment	97	13	8	11[illegible]	6		/118
No. of sinuses	173	94	59	232	82		/326
Control series (diagnostic puncture)	51			51			/51

The weekly changes in resistance are presented in Table 15

In the control series, resistance was normal in all cases.

— Resistance after irrigation

In the sinusitis series, resistance after irrigation was normal in 71.2 % (²²⁴/₃₁₈) slightly elevated in 28.2 % (⁸⁹/₃₁₈) and markedly elevated in 0.6 % (²/₃₁₈) Resistance was normal at diagnostic puncture in 49.1 % (⁵⁸/₁₁₈) during treatment in 68.9 % (⁶²/₉₀) and at the end of treatment in 94.9 % (/₁₁₈)

In the control series, ostial resistance after irrigation was normal in all cases.

Comment Normal ostial resistance corresponding to 0—5 mm Hg occurred before irrigation in 53.1 % and after irrigation in 71.2 %

Ostial resistance was normal in sinusitis at diagnostic puncture in 49.1 % and at the end of treatment in 94.9 of the cases.

Ostial resistance has to be measured after irrigation, since antral secretion obstructing the ostium results in errors in resistance measurements.

6. Recovery

Only cases of acute maxillary sinusitis that recovered were included in this investigation. The weekly cumulative recovery is presented in Table 21. After the first week of treatment no retention of secretion was revealed in 49.2 (⁻⁸/₁₁₈) After the second, the corresponding figure was 84.7 % (¹⁰⁰/ ₁₈)

H. Comparisons between results of clinical observations, ostial patency tests and resistance measurements

1. Ache in relation to ostial patency, resistance and time of recovery

No interrelation was observed between the ache symptom and ostial patency in acute maxillary sinusitis (Table 16).

Ostial resistance had no relation to the ache symptom in sinusitis (Table 17).

Time of recovery was independent of absence or presence of ache symptom in sinusitis (Table 18).

2. X-ray findings in relation to ostial patency and resistance

In the [illegible] series, the ostium was open in 39.3 % ([illegible]) partially open in 7.1 % ([illegible]) and obstructed in 53.6 % ([illegible]) when the antral mucosa was slightly thickened (Table 19). If the mucosa was markedly thickened, the corresponding figures were 12.0 % ([illegible]) 32.0 % ([illegible]) and 56.0 % ([illegible]). In cases where fluid level was roentgenologically demonstrated, the ostium was open in 26.3 % ([illegible]) partially open in 21.1 % ([illegible]) and obstructed in 52.6 % ([illegible]). If the sinus was homogeneously clouded, the ostium was open in 7.4 % ([illegible]) partially open in 23.9 % ([illegible]) and obstructed in 68.7 % ([illegible]).

Comparing the ostial patency in different X-ray findings, it was noted that the ostium was open significantly more often in cases where the antral mucosa was slightly thickened than in cases where either the antral mucosa was markedly thickened ($\chi^2 = 8.06$, df $= 2$) or the sinus homogeneously clouded ($\chi^2 = 9.27$ df $= 2$). There was no significant difference in patency if the antral mucosa was slightly thickened or there was fluid level inside the sinus.

In the sinusitis series, resistance recordings before and after irrigation did not differ significantly from each other in different X-ray findings (Table 20).

In the [illegible] series, the ostium was open in 66.7 % ([illegible]) and partially open in 33.3 % ([illegible]) when the mucosa of the sinus was normal. If the mucosa was slightly thickened, the ostium was open in 58.8 % ([illegible]) partially open in 35.3 % ([illegible]) and obstructed in one case. The ostium of homogeneously clouded sinus was open.

Table 17. *Ache and ostial resistance at diagnostic puncture.*

4 weeks		[illegible]	3
5 weeks	2		2
No. of sinuses	71	47	118

$\chi^2 = 3.08$, df $= 3$

The weekly changes in resistance are presented in Table 15.

In the c o n t r o l series, resistance was normal in all cases.

— *Resistance after irrigation*

In the s i n u s i t i s series, resistance after irrigation was normal in 71.2 % (²³⁹/ₐₙ) slightly elevated in 28.2 % (/ₐₙ) and markedly elevated in 0 6 % (/ₐₙ) Resistance was normal at diagnostic puncture in 49.1 % (⁵⁸/ ₙ) during treatment in 68.9 % (⁶²/ₐₙ) and at the end of treatment in 94.9 % (/ₙ)

In the c o n t r o l series, ostial resistance after irrigation was normal in all cases.

Comment Normal ostial resistance corresponding to 0—5 mm Hg occurred before irrigation in 53.1 % and after irrigation in 71.2 %

Ostial resistance was normal in sinusitis at diagnostic puncture in 49.1 % and at the end of treatment in 94.9 of the ases.

Ostial resistance has to be measured after irrigation since antral secretion obstructing the ostium results in errors in resistance measurements.

G. Recovery

Only cases of acute maxillary sinusitis that recovered were included in this investigation. The weekly cumulative recovery is presented in Table 21. After the first week of treatment no retention of secretion was revealed in 49.2 % (⁵⁸/ₙₙ) After the second, the corresponding figure was 84.7 % (¹⁰⁰/ₙₙ)

2 weeks	8	6	28	70.0	84.7	42
3 weeks	2	2	4	44.4	91.5	8
4 weeks	1	1	6	80.0	98.3	8
5 weeks			2	100.0	100.0	
No. of sinuses	26	25	67			118

If the ostium was obstructed, the penetrance as normal in 19.4 % (/) on sniffing and in 18.0 % (/) on blowing. There was no penetrance on sniffing in 34.7 % (/) and on blowing in 44.4 % (/) In other cases the sniff/blow penetrance was diminished.

In comparing postirrigational results, in the control series the ostial penetrance on sniffing was normal when the ostium was open or partially open. In only two cases where the ostium was obstructed did diminished penetrance occur. The penetrance was diminished on blowing once with open ostium and twice when the ostium was obstructed during respiration. In the remaining cases the penetrance was normal.

Comment. An open or partially open ostium always had sniff/blow penetrance, but in 10.7 % the penetrance was diminished. An obstructed ostium had sniff/blow penetrance in 60.4 % but it was normal in only 1 7 % of the cases. Ostial respiratory obstruction and no penetrance occurred simultaneously in 17.5 % in sinusitis.

5. *Ostial patency and antral pressure return after sniffing and blowing*

In the sinusitis series, return to original level was normal when the ostium was open in 92.6 % (/) after sniffing and in 89.5 % (/) after blowing (Table 23). When the ostium was partially open, the respective values were 67.8 % (/) and 60.9 % (/). With an obstructed ostium, return was normal in 14.9 % (/) after sniffing and in 18.8 % (/) after blowing, if only cases are taken into account where sniffing or blowing produced an antral pressure change.

Table 22. *The ostial sniff/blow penetrance in relation to the ostial patency. Figures refer to numbers of sinuses at postirrigational examination.*

Patency	Antral pressure changes in mm H_2O							
	Sniffing				Blowing			
	> 60	60—?	20—?	0	> 60	60—?	20—	0
Sinusitis series								
Open	92	3			93	2		
Partially open	08	13	8		4	7	8	
Obstructed	28	18	45	60	23	8	49	64
Control series (diagnostic puncture)								
Open	36				35	1		
Partially open	11				11			
Obstructed	2	2			2	1	1	

Table 19. *X-ray findings and ostial postsuctional patency at diagnostic puncture*

X-ray findings	Patency: Open	Partially open	Obstructed	No. of sinuses
Sinusitis series				
Mucosa slightly thickened	11	–	15	28
Mucosa markedly thickened	3	8	14	25
Fluid level	10	8	20	38
Sinus homogeneously clouded	2	7	18	27
No. of sinuses	26	23	67	118
Control series				
Mucosa normal	22	11		33
Mucosa slightly thickened	10	6	1	1[illegible]
Sinus homogeneously clouded	1			1
No. of sinuses	33	17	1	51

Comment. The frequency of obstructed ostia was significantly higher in sinusitis if the x-ray examination revealed marked thickening of the antral mucosa or homogeneous clouding of the sinus, than if the antral mucosa was slightly thickened or there was a fluid level inside the sinus.

Conclusions cannot be drawn about ostial resistance by means of x-ray findings.

3. *Time of recovery and ostial patency*

When the ostium was open at diagnostic puncture 57.7 % (/..) of the sinusitis series were cured within a week (Table 21). When the ostium was partially open recovery occurred in 64.0 % (/..) and in 40.3 % (/..) if the ostium was obstructed. No significant difference between an open and an obstructed ostium was observed as regards the time of recovery. When the time of recovery and the ostial patency were observed during the following weeks, no difference as compared to the recovery of the first week, could be shown.

4. *Ostial patency and penetrance*

In the sinusitis series, the open ostium had diminished penetrance in two cases at diagnostic puncture and in one case during treatment (Table 22). In all other cases, sniff penetrance was normal. When the ostium was open blow penetrance was normal in all cases both at diagnostic puncture and during treatment. At the end of treatment blow penetrance was diminished in two cases.

If the ostium was partially open, the sniff/blow penetrance always produced an antral pressure change. The penetrance of sniffing was diminished in 41 % (/..) and in blowing in 14.9 % (3/..). In all other cases the sniff/blow penetrance was normal.

Table 20. *X-ray findings and ostial resistance at diagnostic puncture*

X-ray findings	Resistance in mm Hg: Before irrigation 0–5	6–50	> 50	After irrigation 0–5	6–50	> 50	No. of sinuses
Mucosa slightly thickened	9	11	8	13	14	1	/28

20 — 1	26	29		55
0	19	43	2	64
No. f sinuses	232	92	2	326

If the ostial penetrance was normal, slightly elevated ostial resistan e after irrigation was observed in 5.9 % (/100) on sniffing and in 4 % (/100) on blowing (Table 25). If there was no penetrance, resistance was normal in 24.0 % (/50) on sniffing and in 29.7 % (19/64) on blowing. In other cases resistance was elevated.

In the ntrol series, esistance was normal in all cases before and after irrigation.

C mment. Ostial respiratory patency and resistance are intercorrelated. Resistance was normal in the open ostium in 97.8 % and in the obstructed ostium in 45.8 %.

When the ostial sniff/blow penetrance was normal, the resistance was also normal after irrigation in 93.4 %. If on the other hand, there was no penetrance, ostial resistance was normal in 27.2 % of the cases.

Table 23. Return of antral pressure after sniffing and blowing in relation to ostial patency determined postirrigationally. Figures refer to numbers of sinuses.

Patency	After sniffing: Normal	Delayed	Valve	No antral pressure change	After blowing: Normal	Delayed	Valve	No antral pressure change
Sinusitis series								
Open	88	1	6		85	3	[illegible]	
Partially open	60	10	18		63	16	19	
Obstructed	14	30	50	50	15	31	34	64
Control series (diagnostic puncture)								
Open	35		1		35		1	
Partially open	8		3		8	1	[illegible]	
Obstructed		1	3			1	3	

Return was delayed with an open ostium in 2.1 % ($^{4}/_{191}$) with a partially open ostium in 14.4 % ($^{?}/_{n}$) and with an obstructed ostium in 33.1 % ($^{?}/_{?}$). The valve frequencies were 0.8 % ($^{?}/_{191}$), 21.3 % ($/_{n}$) and 48.3 % ($^{44}/_{n}$) respectively.

In the control series, pressure return to original level after sniffing and blowing was normal with open ostium in 97.[illegible] % ($^{34}/_{35}$) and with partially open ostium in 7[illegible].7 % (/). Of the four cases where the ostium was obstructed return was delayed in one case, and there was a valve in three cases both on sniffing and blowing.

Comment. In sinusitis antral pressure return to original level after sniffing and blowing was most often not normal when the ostium was obstructed. The return was delayed in 31 % and the valve phenomenon occurred in 20 % of the cases with obstructed ostium.

6. Ostial patency and penetrance in relation to ostial resistance

In the sinusitis series, resistance was normal before irrigation in the open ostium in 8[illegible] % ($^{?}/_{109}$), in the partially open ostium in 67.9 % ($^{57}/_{84}$) and in the obstructed ostium in 15.8 % ($^{?}/_{n}$) (Table 24). In the cases of elevated ostial resistance the incidence of marked elevation, more than 50 mm Hg, was related to the degree of patency disturbance.

After irrigation resistance was normal in the open ostium in 9[illegible].0 % ($^{?}/_{?}$), in the partially open ostium in 83.9 % ($/_{n}$) and in the obstructed ostium in 45.8 % ($^{44}/_{n}$). In all other cases resistance was elevated. At the end of treatment resistance after irrigation was similar to that of the control series in the open ostium in all cases, in the partially open ostium in 9[illegible].4 % ($^{44}/_{n}$) and in the obstructed ostium in 70.[illegible] ($/_{n}$).

Table 24. Ostial patency at postirrigational examination in relation to ostial resistance (mm Hg)

Patency	Before irrigation: 0–5	6–50	> 50	No. of sinuses	After irrigation: 0–5	6–50	> 50	No. of sinuses

20 — 1	28	20		56
0	19	43	2	64
No. f sinuses	232	92	2	326

If the ostial penetrance was normal, slightly elevated ostial resistance after irrigation was observed in 5.9 % (11/[illegible]) on sniffing and in 4 % (/[illegible]) on blowing (Table 23) If there was no penetrance, resistance was normal in 24.0 % (/[illegible]) on sniffing and in 29.7 % (19/[illegible]) on blowing. In other cases resistance was elevated.

In the ontrol series, resistance was normal in all cases before and after irrigation.

C mment Ostial respiratory patency and resistance are intercorrelated. Resistance was normal in the open ostium in 97.0 % and in the obstructed ostium in [illegible].8 %

When the ostial sniff/blow penetrance was normal, the resistance was also normal after irrigation in 93.4 % If, on the other hand, there was no penetrance, ostial resistance was normal in [illegible].2 % of the cases.

Table 23. Return of antral pressure after sniffing and blowing in relation to ostial patency determined postirrigationally. Figures refer to numbers of sinuses.

Patency	After sniffing: Normal	Delayed	Valve	No antral pressure change	After blowing: Normal	Delayed	Valve	No antral pressure change
Sinusitis series

A disadvantage f consecutive measuring is that the peaks of both pressure decrease and increase developed during respiration continuously fluctuate, even in the same person. In present study 25 % was chosen the limit within hich this fluctuation was allo ed to ary i.e. the ostium as still considered open hen the mean peaks f antral pressure decrease during inspiration ere t least 75 % of the corresponding inspiratory pressure decrease in the nasopharynx. The pressures f the nasopharynx and the sinus ere compared w th each other using the means f th inspirat ry pressure decreases.

This rough estimate f the means was proved appropriate by study in which individual ariation as also statistically analysed and compared at the significance lev l of 0.01.

Model experiments wer arranged to study some details pertaining t the patency test. It as sho that circular ostium with as narrow diameter as 0.5 mm transmitted respiratory peak pressures unchanged from the nasal ca ity into the sinus. In the patency tests ith the model, secretion had decisi influen on the results f measurement f the sinus p essures. It as observed that ostial obstruction caused by secretion dis ppeared hen the secretion as removed by sucking through the trocar

I the sinusitis and control series f the present study ostial patency w tested in three phases of the same examination nam ely post sectionally and postirrigationally The latter measurement as pe f rmed fter careful removal by suction t the irrig tion fluid and possible secretion Observ tions made in the same phase f examination ere best suited for compa son nd esult re most representat t ostial patency as tested post sect onally nd ostial penetrance t sniffing and blo ing postirrigationally The difference bet en esult t patency and penetr nce testing due to the different pressures used in testing ostial patency nd penetrance.

Ostial respirat ry obstruction is due either t the lling t mucosa and/or to secretion the tubing or ostial anal. The respiratory p tency t st t kes both possibil ties into consideration simultaneously The use f sniff/blow pressure as t decisi influence in seeking uses t the obstruction. A ollen mucous membrane an be considered cause t ostial obstruction, if sniff/blow pressures cannot be recorded inside the sinus. It is further possibl that ostial obstruction is caused by secretion, en though no antral sniff/blow pressures can be recorded.

Ostial obstruction caused by mucous membrane elling and secretion occurred in present study in 40.8 % nd obstruction caused by mucous membrane swelling only in 1 .5 %

Disturbances t patency such as alve phenomenon and delayed return f pressure in the penetrance test fter sniffing and blowing, are interp eted nly as signs f secretion.

When the ostial resistance was measured before the sinus secretion had been irrigated y the united esistanc f the ostium and the secretio was recorded. A most representat result for the ostial resistance only was obtained when resistance was measured after irrigation. In present sinusitis series, resistance as normal, 0—5 mm Hg, before irrigation in 53.1 % and after irrigation in 71.2 %

2. Ostial pat ncy si usitis

A rding to Drettner (1965e) an ostial obstruction for expiration is present in acute maxillary sinusitis in 76.8 % and f sniffing and blowing here indicated by the term penetrance, in every other case. In this series, the corresponding figures were 32.8 % and 1 .5 % taking the best patency f the three phases of the examination and the penetrance after the irrigation into account.

A al phenomenon or delayed return in the penetrance test oc urred in 60.4 % f these es t the present sinusitis series in which the ostium as obstructed for quiet respiration. The al occurred in this series twic as ften as in that f Drettne (1965e)

The discrepancies between results f the series f Drettner and of present study are pparently due to different methods of investigation, different evaluation f results and also differences in the series. In the present study ostial patency as examined only in reversible ases f acute maxillary sinusitis. Further the details of the examination, the exact phase and relation to irrigation and trials to eliminate the effect f secretion were not given in Drettner' series. The most important reason for the differences bet een Drettner' and the present results is presumably secretion, to which special ttention has been paid in this study

VIII Discussion

A Bacterial findings of sinus secretion

The bacteriological findings in the present series of 118 cases of acute maxillary sinusitis may be considered to correspond to the earlier studies (Urdal & Berdal 1949 Kortekangas, 1963 Lystad et al., 1963 Meinecke 1971 and Axelsson & Brorson 197?) when account is taken of the fairly large variation in the frequencies of different bacteria.

B. Ache in relation to ostial patency resistance and recovery

Flottes et al. (1960) and Drettner (1960) observed that test subjects had no ache even though the antral pressure was decreased to 300—400 mm H_2O below the ambient atmospheric pressure This, of course, is only possible when the ostium is obstructed.

Sluder's (1927) conclusion that ache results from an antral pressure decrease caused by oxygen resorption was recently partly confirmed by Aust & Drettner (1974b) who found some correlation between pain in the region of the paranasal sinuses and low oxygen content inside the sinus.

This series agrees with Drettner's (1966) observation that ache symptom and ostial patency are not mutually correlated. Further in this series no conclusions can be drawn about the ostial resistance and the time of recovery on the grounds of the ache.

C. X ray findings in relation to ostial patency and resistance

The more marked the x ray changes, the more probable is the presence of secretion in the sinus (Hinde, 1950 Vuorinen et al., 1962 McNeill 1963) When a fifth projection, occipitomental with the head horizontal and the affected side downwards, is added to the so-called standard projections, occipitofrontal occipitomental full axial and lateral, antral secretion can be demonstrated by means of x ray examination in 88 % of cases in which antral mucous membrane thickening is seen and the puncture positive (Axelsson et al., 1970)

In this series, using three standard projections, the presence of secretion was demonstrated by x ray in only every third case, although changes were seen in all of them.

Thus, to my knowledge is the first study in which x ray findings have been compared with the results of ostial patency and resistance tests. According to present observations, an ostial obstruction was significantly more frequent in cases in which marked mucous membrane changes were present or the sinus was homogeneously clouded than in cases in which the mucous membrane changes were slight or in which there was an antral fluid level. From this observation, it can be concluded that the antral mucous membrane changes, i.e. swelling extend into the ostium producing similar alterations in the ostial patency

As discussed in the next chapter respiratory obstruction in the ostium can be due to secretion, as well as to thickening of the mucous membrane of the ostium. The observation that ostial resistance was independent of x ray findings supported the opinion that respiratory obstruction in the ostium is often caused by secretion in the ostium.

D Ostial patency

1 Methods

Ostial patency test is a comparison of pressure variation inside the sinus and the corresponding nasal cavity or nasopharynx These pressures can be recorded either consecutively or simultaneously With simultaneous recording, introduction of a catheter in the middle meatus as in Drettner's (1965c) technique can be difficult and often cause discomfort to the patient. For this reason, a consecutive recording was chosen in the method of this study and the reference pressure was recorded by means of the anterior rhinomanometric technique.

A disadvantage of consecutive measuring is that the peaks of both pressure decrease and increase developed during respiration continuously fluctuate, even in the same person. In present study 25 % was chosen as the limit within which this fluctuation was allowed to vary, i.e. the ostium was still considered patent when the mean peaks of antral pressure decrease during inspiration were at least 75 % of the corresponding inspiratory pressure decrease in the nasopharynx. The pressures of the nasopharynx and the sinus were compared with each other using the means of five inspiratory pressure decreases.

This rough estimate of the means was proved appropriate by a study in which individual variation was also statistically analysed and compared at the significance level of 0.01.

Model experiments were arranged to study some details pertaining to the patency test. It was shown that a circular ostium with as narrow diameter as 0.5 mm transmitted respiratory peak pressures unchanged from the nasal cavity into the sinus. In the patency tests with the model, secretion had a decisive influence on the results of measurement of the sinus pressures. It was observed that ostial obstruction caused by secretion disappeared when the secretion was removed by sucking through the trocar.

In the sinusitis and control series of the present study ostial patency was tested in three phases of the same examination: initially, post-suctionally and post-irrigationally. The latter measurement was performed after careful removal by suction of the irrigation fluid and possible secretion. Observations made in the last phase of examination were best suited for comparison and results were most representative of ostial patency was tested post-suctionally and ostial penetrance for sniffing and blowing postirrigationally. The difference between results of patency and penetrance testing is due to the different pressures used in testing ostial patency and penetrance.

Ostial respiratory obstruction is due either to the swelling of mucosa and/or to secretion in the tubing or ostial canal. The respiratory patency test takes both possibilities into consideration simultaneously. The use of sniff/blow pressures was of decisive influence in solving cases of the obstruction. Swollen mucous membrane can be considered the cause of ostial obstruction, if sniff/blow pressures could be recorded inside the sinus. It is further possible that ostial obstruction is caused by secretion, even though no antral sniff/blow pressures can be recorded.

Ostial obstruction caused by mucous membrane swelling and secretion occurred in present study in 40.8 % and obstruction caused by mucous membrane swelling only in 1.6 %.

Disturbances of patency such as valve phenomenon and delayed return of pressure in the penetrance test after sniffing and blowing, are interpreted only as signs of secretion.

When the ostial resistance was measured before the sinus secretion had been irrigated away the united resistance of the ostium and the secretion was recorded. A most representative result for the ostial resistance only was obtained when resistance was measured after irrigation. In present sinusitis series, resistance was normal, 0–5 mm Hg, before irrigation in 53.1 % and after irrigation in 71.2 %.

2. *Ostial patency in sinusitis*

According to Drettner (1965c) an ostial obstruction for respiration is present in acute maxillary sinusitis in 68 % and for sniffing and blowing, here indicated by the term penetrance, in every other case. In this series, the corresponding figures were 32.8 % and 17.5 % taking the best patency of the three phases of the examination and the penetrance after the irrigation into account.

A valve phenomenon or delayed return in the penetrance test occurred in 50.4 % of those cases of the present sinusitis series in which the ostium was obstructed for quiet respiration. The valve occurred in this series twice as often as in that of Drettner (1965c).

The discrepancies between results of the series of Drettner and of present study are apparently due to different methods of investigation, different evaluation of results and also differences in the series. In the present study ostial patency was examined only in reversible cases of acute maxillary sinusitis. Further the details of the examination, the exact phase and relation to irrigation and trials to eliminate the effect of secretion were not given in Drettner's series. The most important reason for the differences between Drettner's and the present results is presumably secretion, to which special attention has been paid in this study.

Kerekes (1934) was the first to point out that ostial patency becomes normal as soon as sinusitis is cured, which is confirmed by the present study. A respiratory ostial obstruction was present at diagnostic puncture in 56.8 % and at the end of treatment in 12.7 %, which corresponds to the result in the control series. There was no sniff/blow penetrance at diagnostic puncture in every fourth case and at the end of treatment in 5.6 % of the cases.

The effect of sniff/blow on the ostial patency corresponded to Drettner's earlier observations, according to which an opening effect occurred in every fourth case when the ostium was obstructed. The fact that also the opposite obstructive effect occurred on sniffing and blowing in 2.6 % of the cases can be explained through movements of the secretion obstructing either the ostium or the trocar.

E. Ostial resistance in sinusitis

According to the investigations of Drettner (1965a) and Zippel & Meier (1968) the ostial resistance is normal, 10—25 mm H_2O, in every second case in maxillary sinusitis. The same result was obtained in the present study when the united resistance of the ostium and secretion was measured, i.e. the recordings were performed before irrigation.

Five mm Hg was taken as the upper limit of normal resistance in the present study. This value was taken from the results obtained in the control series and is only one fourth of what had been used in the above-mentioned investigations.

When resistance was measured after irrigation it was normal in maxillary sinusitis in 71.. %. Drettner's observation, that the return to normal of resistance takes place as soon as the sinusitis is cured, was confirmed by the study in which resistance was elevated at diagnostic puncture in every second case and at the end of treatment in ..1 % of the cases. In the present writer's opinion, return to normal resistance is due to decreased inflammatory swelling in the ostial mucosa during recovery.

Ostial obstruction has been considered the reason for retention of secretion inside the sinus (e.g. Naumann, 1965). In the writer's opinion, ostial obstruction is rather a result of the inflammatory process on the mucosa. This opinion is supported by the fact that a patent ostium is frequently found in cases of sinusitis even with abundant secretion in the sinus.

Consequently the greatest significance of ostial patency tests is, that they allow alterations in ostial patency to be observed during infection. When the ostium remains obstructed for several weeks in spite of therapy an irreversible inflammation is obvious.

By using ostial resistance measurement, information can be gained about ostial function. However the exactness of results of ostial patency tests makes these preferable to resistance measurement in spite of the following advantages of resistance measurement: uncomplicated equipment, ease of measurement and absence of sources of error. Resistance measurements cannot replace patency tests, but they offer some additional information as to ostial function and degree of ostial obstruction.

XI Summary

The present study consisting of 118 maxillary sinusitis cases, of such a degree of cateness that there was retention of secretion inside the sinus, the bacteriological findings corresponded to those of earlier investigations.

It was observed that there was no relation between ache and ostial patency or resistance. Furthermore, time of recovery from sinusitis was independent of whether ache was present at the beginning of infection or not.

At the X-ray examination, which was performed immediately before diagnostic puncture, the occipitofrontal, occipitomental and lateral projections were used. The findings were defined as follows: normal, slightly or markedly thickened mucosa, fluid level inside the sinus and homogeneously clouded sinus. When the mucosa was markedly thickened or the sinus homogeneously clouded, ostial obstruction was more common than in cases in which the mucosa was slightly thickened or there was fluid level inside the sinus. No correlation was observed between X-ray findings and ostial resistance.

Ostial patency was determined by comparing pressure variation in the nasopharynx, measured by anterior rhinomanometry and in the maxillary sinus measured through a trocar. The measurements were performed consecutively on the sinus and the nasopharynx, and peak values during inspiration were evaluated. Because of natural variation of these values, the ostium was considered open when the peak values of antral pressure decreases during inspiration were at least 75 % of the corresponding inspiratory pressure decreases in the nasopharynx. The suitability of this evaluation was proved by statistical analyses of the material.

Ostial patency and penetrance were tested in three phases of the same examination: native, postsuctionally and postirrigationally. Optimal information about ostial patency was gained when the most normal patency was taken into account. When ostial patency and penetrance were tested in only one phase of the same examination, the patency was most often normal postsuctionally and the sniff/blow penetrance postirrigationally.

Ostial respiratory obstruction is due to the swelling of mucosa and/or to secretion in the ostial canal. When the ostial sniff/blow penetrance is tested, ostial patency caused by mucous membrane swelling can be differentiated from that caused by secretion.

Ostial resistance was measured before and after irrigation. When resistance was measured before irrigation, the united resistance of ostium and secretion was recorded. A more reliable result about the ostial resistance was obtained when resistance was measured after irrigation.

In the sinusitis series, ostial patency tests and resistance measurements were repeated weekly until recovery. The ostium was found to be obstructed for respiration at diagnostic puncture in 60.8 % and at the end of treatment in 12.7 %, corresponding to that in healthy test subjects. The frequencies of open, partially open and obstructed ostia did not differ significantly when there was secretion inside the sinus.

There was no ostial sniff/blow penetrance in 20.7 % at diagnostic puncture and in 3.5 % at the end of treatment. A valve phenomenon, delayed pressure return after sniffing and blowing, probably caused by secretion, occurred in 50.4 % of ostia obstructed for respiration. The effect of sniff/blow on ostial respiratory patency was observed in 6.2 %.

In present study it was observed that the return to normal of ostial resistance took place as soon as the sinusitis was cured. At diagnostic puncture, resistance was elevated in 50.9 % and at the end of treatment in 5.1 %.

Kerekes (1934) was the first to point out that ostial patency becomes normal as soon as sinusitis is cured, which is confirmed by the present study. A respiratory ostial obstruction was present at diagnostic puncture in 56.8 % and at the end of treatment in 1.7 % which corresponds to the result in the control series. There was no sniff/blow penetrance at diagnostic puncture in every fourth case and at the end of treatment in 5.6 % of the cases.

The effect of sniff/blow on the ostial patency corresponded to Drettner's earlier observations, according to which an opening effect occurred in every fourth case when the ostium was obstructed. The fact that also the opposite obstructive effect occurred on sniffing and blowing in 6 % of the cases can be explained through movements of the secretion obstructing either the ostium or the trocar.

E. Ostial resistance in sinusitis

According to the investigations of Drettner (1965a) and Zippel & Meier (1968) the ostial resistance is normal, 10—5 mm H_2O, in every second case in maxillary sinusitis. The same result was obtained in the present study when the united resistance of the ostium and secretion was measured, i.e. the recordings were performed before irrigation.

Five mm Hg was taken as the upper limit of normal resistance in the present study. This value was taken from the results obtained in the control series and is only one fourth of what had been used in the above-mentioned investigations.

When resistance was measured after irrigation, it was normal in maxillary sinusitis in 71.2 %. Drettner's observation, that the return to normal of resistance takes place as soon as the sinusitis is cured, was confirmed by this study, in which resistance was elevated at diagnostic puncture in every second case and at the end of treatment in 5.1 % of the cases. In the present writer's opinion, return to normal resistance is due to decreased inflammatory swelling in the ostial mucosa during recovery.

Ostial obstruction has been considered the reason for retention of secretion inside the sinus (e.g. Naumann 1965). In the writer's opinion, ostial obstruction is rather a result of the inflammatory process on the mucosa. This opinion is supported by the fact that a patent ostium is frequently found in cases of sinusitis even with abundant secretion in the sinus.

Consequently the greatest significance of ostial patency tests is, that they allow alterations in ostial patency to be observed during infection. When the ostium remains obstructed for several weeks in spite of therapy an irreversible inflammation is obvious.

By using ostial resistance measurement information can be gained about ostial function. However, the exactness of results of ostial patency tests makes these preferable to resistance measurement in spite of the following advantages of resistance measurement: uncomplicated equipment, ease of measurement and absence of sources of error. Resistance measurements cannot replace patency tests, but they offer some additional information as to ostial function and degree of ostial obstruction.

XI Summary

The present study consisting of 119 maxillary sinusitis cases, of such a degree of acuteness that there was retention of secretion inside the sinus, the bacteriological findings corresponded to those of earlier investigations.

It was observed that there was no relation between ache and ostial patency or resistance. Furthermore, time of recovery from sinusitis was independent of whether ache was present at the beginning of infection or not.

At the x-ray examination, which was performed immediately before diagnostic puncture, the occipitofrontal, occipitomental and lateral projections were used. The findings were defined as follows: normal, slightly or markedly thickened mucosa, fluid level inside the sinus and homogeneously clouded sinus. When the mucosa was markedly thickened or the sinus homogeneously clouded, ostial obstruction was more common than in cases in which the mucosa was slightly thickened or there was fluid level inside the sinus. No correlation was observed between x-ray findings and ostial resistance.

Ostial patency was determined by comparing pressure variations in the nasopharynx, measured by anterior rhinomanometry, and in the maxillary sinus measured through a trocar. The measurements were performed simultaneously on the sinus and the nasopharynx, and peak slopes during inspiration were evaluated. Because of natural variations of these slopes, the ostium was considered open when the peaks of antral pressure decreases during inspiration were at least 75 % of the corresponding inspiratory pressure decreases in the nasopharynx. The suitability of this evaluation was proved by a statistical analysis of the variation.

Ostial patency and penetrance were tested in three phases of the same examination: nasally, postaspirationally and postirrigationally. Optimal information about ostial patency was gained when the most normal patency was taken into account. When ostial patency and penetrance were tested in only one phase of the same examination, the patency was most often normal postaspirationally and the sniff/blow penetrance postirrigationally.

Ostial respiratory obstruction is due to the swelling of mucosa and/or to secretion in the ostial canal. When the ostial sniff/blow penetrance is tested, ostial patency caused by mucous membrane swelling can be *differentiated from* that caused by secretion.

Ostial resistance was measured before and after irrigation. When resistance was measured before irrigation, the united resistance of ostium and secretion was recorded. A more reliable result about the ostial resistance was obtained when resistance was measured after irrigation.

In the sinusitis series, ostial patency tests and resistance measurements were repeated weekly until recovery. The ostium was found to be obstructed for respiration at diagnostic puncture in [illegible] % and at the end of treatment in 1[illegible].7 % corresponding to that in healthy test subjects. The frequencies of open, partially open and obstructed ostia did not differ significantly when there was secretion inside the sinus.

There was no ostial sniff/blow penetrance in 28.7 % at diagnostic puncture and in 5.5 % at the end of treatment. A valve phenomenon or delayed pressure return after sniffing and blowing, probably caused by secretion, occurred in 60.4 % of ostia obstructed for respiration. The effect of sniff/blow on ostial respiratory patency was observed in 8.2 %.

In present study it was observed that the return to normal of ostial resistance took place as soon as the sinusitis was cured. At diagnostic puncture, resistance was elevated in 60.9 % and at the end of treatment in 5.1 %.

Kerekes (1934) was the fi t to point out that ostial patency becomes n rmal as soon as sinusitis is cured, which is confirmed by the present study A respiratory ostial obstruction was present at diagnostic puncture in 50.8 % an l at the end of treatment in 12.7 % which corresponds to the result in the control series. There was no sniff/blow penetrance at diag nostic puncture in every fourth case and at the end of treatment in 5.5 % of the cases.

The effect of sniff/blow on the ostial patency corresponded to Drettner's earlier observations, according to which an opening effect occurred in every fourth case when the ostium was obstructed. The fact that also the opposite obstructive effect occurred on sniffing and blow ing in 2.6 % of the cases can be explained through movements of the secretion obstructing either the ostium or the trocar

E. Ostial resistance in sinusitis

According to the investigations of Drettner (1965a) and Zippel & Meier (1968) the ostial resistance is normal 10—3 mm H_2O in every second case in maxillary sinusitis. The same result was obtained in the present study when the united resistance of the ostium and secretion was measured i.e. the recordings were performed before irrigation

Five mm Hg was taken as the upper limit of normal resistance in the present study This value was taken from the results obtained in the control series and is only one fourth of what had been used in the above-mentioned investigations.

When resistance was measured after irrigation it was normal in maxillary sinusitis in 71.2 % Drettner's observation that the return to normal of resistance takes place as soon as the sinusitis is cured, was confirmed by this study in which resistance was elevated at diag nostic puncture in every second case and at the end of treatment in 5.1 % of the cases. In the present writer's opinion, return to normal resistance is due to decreased inflammatory swelling in the ostial mucosa during recovery

Ostial obstruction has been considered the reason for retention of secretion inside the sinus (e.g Naumann 1965) In the writer's opinion, ostial obstruction is rather a result of the in flammatory process on the mucosa. This opinion is supported by the fa t that a patent ostium is frequently found in cases of sinusitis even with abundant secretion in the sinus.

Consequently the greatest significance of ostial patency tests is, that they allow alter ations in ostial patency to be observed during infection. When the ostium remains obstructed for several weeks in spite of therapy an irreversible inflammation is obvious.

By using ostial resistance measurement, in formation can be gained about ostial function. However the exa tness of results of ostial patency tests makes these preferable to resistan e measurement in spite of the following advantages of resistance measurement uncomplicated equipment ease of measurement and absence of sources of error Resistance measurements cann t replace patency tests, but they offer some additional inf rmation as to ostial fun tion and degree of ostial obstruction.

X. Acknowledgements

I am grateful to my teacher in oto-laryngology Professor Otto H. Meurman, M.D., Head of the Otolaryngological University Clinic, Turku, for his continued interest in the progress of this study and for his valuable criticism of the manuscript.

I would like to address my best thanks to Associate Professor A. E. Kortekangas, M.D., who planned the rhinomanometric recording equipment of the Otolaryngological Clinic in Turku which made it possible to carry out this study. I especially want to thank him for choosing the subject of this study and for planning the methodology and, above all, for the criticism that has been needed at all stages of the study.

I am very grateful to Professor Eero Mustakallio, M.D., Head of the Department of Medical Microbiology, University of Turku, and Professor Pekka Virtama, M.D., Head of the Department of Radiology, University Hospital, Turku, for giving me access to the facilities of their departments.

I also wish to thank Mrs. Aili Ryynänen, M.A., and her assistants for their help in collecting the literature and Mr. Pertti [illegible], M.Sc., and Mr. Seppo [illegible], M.Sc., for their help in the statistical analysis of the results.

My sincere thanks are due to Mrs. Aira Thölix, M.A., for translating the manuscript into English and to Mr. Colin Black, [illegible], B.A., for revising the translation.

Last but not least, I wish to thank my wife for her help in performing model experiments and for her untiring patience and support during the course of this study.

Part I Basic Study of Nasopharyngitis

Part I

Basic Study of Nasopharyngitis

1 Introduction

Nasopharyngitis, a peculiar diagnosis, should be news to the readers. This term probably cannot be found in any textbook of medicine, any reference book of otorhinolaryngology or in any literature hitherto published. Nasopharyngitis, the main subject of my lifework, is still an unknown problem of the medical world, as it were, a desert island in the sea however this desert island is really a treasury of medical science, the development of which may suggest the possibility of doing scientific reevaluation of not a little part of the acquired knowledge of medicine. The nasopharynx is, as will be stated in the following, an entrance, through which bacterial organism first gain entrance into the body and most people probably have a standing process of inflammation in this part of the body The most definite of the acute symptoms of such inflammation is the "common cold" and examination has proved the standing process of chronic inflammation to be a cause of allergy collagen diseases, diseases of the autonomic nervous system and various other diseases derived therefrom. For clarifying the mechanisms such as antibody production, fibrinolysis, pituitary-adrenal system, autonomic nervous mechanism, etc., which are supposed to be recovery mechanisms of the body the concept of nasopharyngitis will make an epoch and secondarily influence the interpretation of pathological mechanisms or the therapy of various diseases. From the standpoint nasopharyngitis many useless studies have been attempted in the present medical world.

The fact that such an important but single inflammatory focus has remained up to the present unnoticed by the medical eye, is astounding however a reason for this is that there are few local symptoms referable to nasopharyngitis. Since no local symptoms are presented from the beginning, the patients do not make any complaints, so that the physicians have likely had no opportunity of making these patients a subject of study

Another reason lies in the fact that the inflammation in this part displays only a few objective signs therefore, only redness is to be found even by an accurate observation with nasopharyngoscope or posterior rhinoscopy so that it will occasionally be overlooked. My study begins with the microscopic observation of the smears prepared by swabs obtained from the mucosa, for only in this way the existence of nasopharyngitis can be confirmed. My study is briefly outlined in due order in what follows.

Part II Clinical Aspects of Nasophryngitis

Part I

Basic Study of Nasopharyngitis

I Introduction

Nasopharyngitis, peculiar diagnosis, should be new to the readers. This term probably cannot be found in any textbook of medicine any reference book of otorhinolaryngology or in any literature hitherto published. Nasopharyngitis, the main subject of my lifework, is still an unknown problem of the medical world, as it were, a desert island in the sea however this desert island is really a treasury of medical science, the development of which may suggest the possibility of doing a scientific reevaluation of not a little part of the acquired knowledge of medicine. The nasopharynx is, as will be stated in the following, an entrance, through which bacterial organism first gain entrance into the body and most people probably have a standing process of inflammation in this part of the body The most definite of the acute symptoms of such inflammation is the common cold and examination has proved the standing process of chronic inflammation to be a cause of allergy collagen diseases, diseases of the autonomic nervous system and various other diseases derived therefrom. For clarifying the mechanisms such as antibody production, fibrinolysis, pituitary adrenal system, autonomic nervous mechanism, etc., which are supposed to be recovery mechanisms of the body the concept of nasopharyngitis will make an epoch and secondarily influence the interpretation of pathological mechanisms or the therapy of various diseases. From the standpoint nasopharyngitis many useless studies have been attempted in the present medical world.

The fact that such an important but single inflammatory focus has remained up to the present unnoticed by the medical eye, is astounding however a reason for this is that there are few local symptoms referable to nasopharyngitis. Since no local symptoms are presented from the beginning, the patients do not make any complaints, so that the physicians have likely had no opportunity of making these patients a subject of study

Another reason lies in the fact that the inflammation in this part displays only a few objective signs therefore, only redness is to be found even by an accurate observation with nasopharyngoscope or posterior rhinoscopy so that it will occasionally be overlooked. My study begins with the microscopic observation of the smears prepared by swabs obtained from the mucosa, for only in this way the existence of nasopharyngitis can be confirmed. My study is briefly outlined in due order in what follows.

2 Anatomy of the Nasopharynx

The nasopharynx is an elongated space extending posteriorly from the nasal cavities. The junction between the nasal cavities and the nasopharyngeal cavity corresponds to the choanae the posterior openings of the nasal fossae, closely adjacent to the posterior end of the nasal septum

The nasal septum is united with the hard palate, while the base of the nasopharynx is found by the so-called soft palate a non-osseous part of the palate. The nasopharynx is, therefore the space at the back of the soft palate, and its base is formed by the soft palate itself. The posterior wall of the nasopharynx is the frequent site of adenoid growth in the pharyngeal tonsils, and the bilateral pharyngeal openings of the auditory tube open on its lateral walls (Fig 1)

The epithelial cells lining the nasopharyngeal cavity are ciliated and columnar in shape. It is just the same with the mucosal epithelium

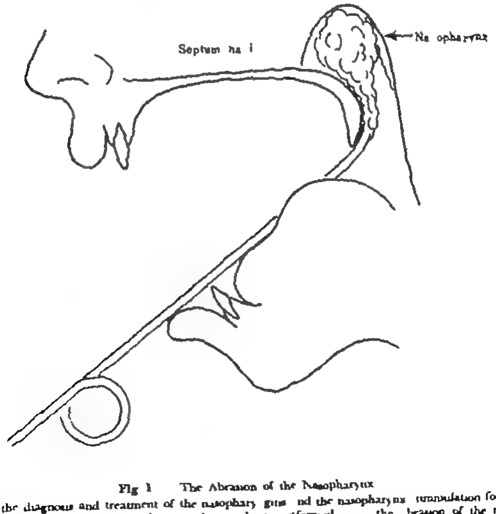

Fig 1 The Abrasion of the Nasopharynx

For the diagnosis and treatment of the nasopharyngitis and the nasopharynx stimulation for the observation of general reactions, this procedure is always performed. The abrasion of the nasopharynx is the preceding act to realize the study of all subjects described in this paper

For the treatment 1 ZnCl solution or other slight corrosive materials with some anesthetic are applied and at the same time the same abrasion is given from the nasal side with nasal cotton applicator to complete the treatment.

of the nasal cavities, larynx, trachea, etc. and is entirely different from that of the other parts of the pharynx, i.e. of the meso- and hypopharynx. In other words, the epithelial cells of the meso- and hypopharynx, in contrast to those of the nasopharynx, are a stratified, squamous nature. By reason of this fact it is indeed wrong to designate the nasopharynx as an epipharynx forming one part of the pharynx. The nasopharynx should be considered as one organ composing a part of the respiratory tract just as the nasal cavity, larynx or trachea.

3 Physiology of the Nasopharynx

The nasopharynx differs not only in its structure from the other parts of the pharynx, as mentioned in the preceding paragraph, but also in its function. The role of the pharynx, namely is the downward transportation of food substances in contact with its surface however the nasopharynx does not play such a role. The food particles do not slide upon the nasopharyngeal surface. It is only the air of respiration that touches the nasopharynx on its surface.

The irritation of the nasopharynx, as stated in the following can produce reflex actions with decided significance to the organism but little is usually known about the matter. It should also be emphasized here that the reflex actions of the nasopharynx also differ widely from those of the pharynx. Namely the reflex actions of the pharynx are the so-called vomiting actions, whereas those of the nasopharynx are not vomiting but sneezing actions, as caused by irritation for instance, of the nasal mucosa. The nasopharynx therefore differs widely from the pharynx not only in morphological structure of the epithelium but also in physiological actions.

The air inhaled through the nostrils, as stated in the preceding paragraph, arrives at the nasopharynx via the choanae, at which the current is bent downward, and flows into the larynx and trachea. The air flowing out through bilateral narrow nasal cavities abruptly into the nasopharynx becomes turbulent and will be drawn further downward along the nasopharyngeal wall, especially its bottom, the dorsal surface of the soft palate; however, on this occasion most of the dust particles in the air with their bacteria attach themselves to the nasopharyngeal wall, and stimulate its mucosal surface physically as well as chemically, so that interruption of the ciliary motion of mucosal epithelium, invasion of dust particles into the mucosa, inflammation, bacterial infections, etc. take place. As long as man breathes through the nose, these stimulations will always be present, so the practical features of the thus occurring nasopharyngitis should be described.

1) Nasopharyngitis in Autopsy Cases

To study the practical state of nasopharyngeal infections, the soft palate of 191 cadavers of various age was examined histopathologically (TAKAHASHI, 1973). Only those subjects were carefully selected and studied, in which clinically no oto-rhino-pharyngo-laryngological findings had been obtained; the number of these cadavers of each age group is given in Table 1.

Table 1. Number of subjects of histological observation of nasopharyngitis

New born–1 mon.		30 cases
1 mon.	1 y	18
1	10 y	18
10	20 y	15
20	30 y	20
30	40 y	10
40	50 yr	25
50	60 y	40
60	70 y	20
70	80 y	17
total		191

In these cadavers inflammatory lesions on the dorsal surface of the soft palate were examined; marked inflammatory changes were found even in the nasopharyngeal mucosa of a newborn infant which died 12 hours after birth.

About the dorsal surface of the soft palate of the cadavers, especially of newborn infants and of infants aged less than 1 month, an inflammation (chiefly cell infiltration, etc. in histology) rate of 76%, i.e. 23 out of 30 cases, was found, and the appearance rate of leucocytes was 78%. The appearance rate of leucocytes, therefore, runs almost in parallel with the histological aspects of inflammation. In such an early period of life, however, the inflammation itself in each individual case was not always conspicuous. There were indeed exceptions, in which marked inflammatory lesions with leucocytic emigration through the epithelium and its desquamation were observed.

As reasons for the fact that the inflammation of the nasopharynx is variably intense at its primary infection, though they are not entirely known, various factors are considered, such as toxicity of bacteria, sensitivity of the individuals, etc. The effects of the inflammation on the whole body, however, for several reasons as will be mentioned later, should differ in relation to the intensity of the inflammation itself. So-called exudative diathesis or asthenic constitution from infancy would seem to appear in such individuals as are profoundly influenced by primary infection. One of the most important factors determining the intensity of infections would possibly be the period of its onset, i.e. whether the infection occurs early or late in infancy. We intend to make a study of the reactions in response to infections, by exposing germ-free animals at various stages to the external world.

In individuals of from 1 to 10 years of age the histological inflammation rate was 83%, whereas the appearance rate of leucocytes was much decreased, to as little as 16%. The incidence of nasopharyngeal infection increases gradually after birth, and in the histological features of infants over 1 year of age lymphocytes and

plasma cells begin to increase and leucocytes to decrease. Thus the inflammation after the primary infection progresses gradually into the *chronic stage*.

This tendency of events grows further with age and at least over 25 years of age the appearance rate of leucocytes decreases further with increasing inflammation rate to the contrary and about from this period Russell's bodies appear beneath the epithelium (5–10%) and remain till an advanced age. Between 20 and 30 years of age the rate of inflammation and appearance of leucocytes is 90 % and 30 % (6 out of 20 cases) respectively which respectively *further* increases and decreases between 40 and 50 years of age. Between 50 and 60 years of age inflammation occurs and leucocytes appear in 95 % and 11 respectively but between 70 and 85 years of age the rate of pathological inflammation and appearance of leucocytes is 95 % and 31 % respectively.

From these observations no definite tendency in the appearance rate of leucocytes was to be found however the inflammation itself becomes increasingly intense with age, so that this indicates considering the personal history throughout the life that at least the majority of persons are now suffering or once suffered from nasopharyngitis.

No definite tendency was found in relation to the appearance rate of leucocytes and age because as factors causing acute exacerbation of inflammation not only age alone but also various other factors should be considered, such as air contamination etc. We carried out for instance, a study on the state of the nasopharynx of laryngectomized and tracheotomized patients, a possible key also to the study of the air con*tamination* and the results obtained are as follows. In these patients the possibility of postoperative infections does not need to be taken into consideration for the air does not flow through the nasopharynx during respiration.

2) Course of Nasopharyngitis in Laryngectomized and Tracheotomized Patients

The subjects of the experiment were as given in Table 2 seven laryngectomized and 2 tracheotomized individuals hence 9 cases in all. In

Table 2 Cases of laryngectomy and tracheotomy

Case No.	Age	Sex	Chief complaint	Diagnosis	Operation
1	73	M	hoarseness	laryngeal ca.	laryngectomy
2	62	M	hoarseness	laryngeal ca.	laryngectomy
3	58	M	dyspnoe	laryngeal ca.	laryngectomy
4	47	M	dyspnoe	laryngeal ca.	laryngectomy
5	49	M	dyspnoe	laryngeal ca.	laryngectomy
6	64	M	hoarseness	laryngeal ca.	laryngectomy
	63	F	dyspnoe	laryngeal ca.	laryngectomy
8	53	F	hoarseness	laryngeal mycosis	tracheotomy
9	66	M	hoarseness	laryngeal ca.	tracheotomy

each case cytological examination and bacteriological streaking with identification were done on the materials from the nasopharynx before operation.

Case

Y H. 58y M. Laryngectomy due to Laryngeal Carcinoma.

In this case the exfoliation of epithelial cells from the nasopharynx was marked prior to operation, but decreased rather soon after operation. The wandering cells, though they were not so numerous from the beginning, disappeared completely 3 months later (Fig 2). Slight nasopharyngeal hemorrhages due to streaking (existence of slight erosion is considered) also disappeared soon. Before operation a moderate content of staphylococci and gramnegative bacilli was found however about 3 months later staphylococci and bacilli gradually decreased in number and disappeared.

As stated above the inflammatory state of the nasopharynx will gradually be improved by laryngectomy or tracheotomy however the progress of the improvement is extremely slow and differs widely from that caused by local treatment. From the above we know that the healing of the inflammation is interrupted by constant irritation due to the flow of (contaminated) respiratory air through the nasopharynx, and on the contrary the inflammation will improve spontaneously if the respiratory air does not flow through.

3) Nasopharyngeal Infections of the Newborn Infants

The period of the primary occurrence of infections in the nasopharyngeal mucosa of the neonatal infant is a matter of particular interest. This region is probably the primary site of air borne infections deep in the organism. *Suzuki (1968) in our clinic* examined in detail

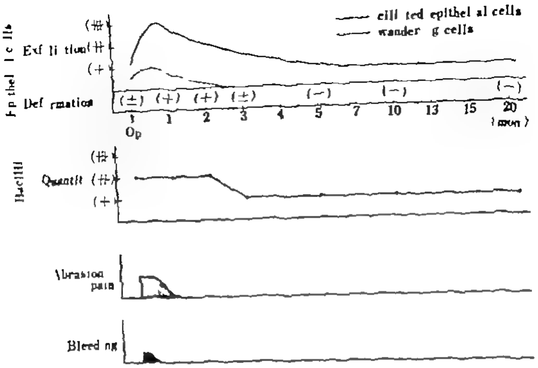

Fig. 2. Course of nasopharyngitis of patient with laryngeal carcinoma (Y.H. 50y. M.)

Table 3 Comparison of nasopharyngeal cytology before and after laryngectomy and tracheotomy

plasma cells begin to increase and leucocytes to decrease. Thus the inflammation after the primary infection progresses gradually into the chronic stage

This tendency of events grows further with age and at least over 25 years of age the appearance rate of leucocytes decreases further with increasing inflammation rate to the contrary and about from this period Russell's bodies appear beneath the epithelium (5–10 %) and remain till an advanced age. Between 20 and 30 years of age the rate of inflammation and appearance of leucocytes is 90 % and 30 % (6 out of 20 cases) respectively which respectively further increases and decreases between 40 and 50 years of age. Between 50 and 60 years of age inflammation occurs and leucocytes appear in 95 % and 11% respectively but between 70 and 85 years of age the rate of pathological inflammation and appearance of leucocytes is 95 % and 31% respectively

From these observations no definite tendency in the appearance rate of leucocytes was to be found however the inflammation itself becomes increasingly intense with age, so that this indicates, considering the personal history throughout the life that at least the majority of persons are now suffering or once suffered from nasopharyngitis

No definite tendency was found in relation to the appearance rate of leucocytes and age, because as factors causing acute exacerbation of inflammation not only age alone but also various other factors should be considered such as air contamination etc We carried out for instance a study on the state of the nasopharynx of laryngectomized and tracheotomized patients, a possible key also to the study of the air contamination and the results obtained are as follows In these patients the possibility of postoperative infections does not need to be taken into consideration for the air does not flow through the nasopharynx during respiration

2) Course of Nasopharyngitis in Laryngectomized and Tracheotomized Patients

The subjects of the experiment were as given in Table 2 seven laryngectomized and 2 tracheotomized individuals hence 9 cases in all In each case cytological examination and bacteriological streaking with identification were done on the materials from the nasopharynx before operation.

Table 2 Cases of laryngectomy and tracheotomy

Case
Y H 58y M Laryngectomy due to Laryngeal Carcinoma.
In this case the exfoliation of epithelial cells from the nasopharynx was marked prior to operation, but decreased rather soon after operation. The wandering cells, though they were not so numerous from the beginning disappeared completely 3 months later (Fig 2) Slight nasopharyngeal hemorrhages due to streaking (existence of slight errosion is considered) also disappeared soon. Before operation a moderate content of staphylococci and gramnegative bacilli was found however about 3 months later staphylococci and bacilli gradually decreased in number and disappeared

As stated above the inflammatory state of the nasopharynx will gradually be improved by laryngectomy or tracheotomy however the progress of the improvement is extremely slow and differs widely from that caused by local treatment From the above we know that the healing of the inflammation is interrupted by constant irritation due to the flow of (contaminated) respiratory air through the nasopharynx, and on the contrary the inflammation will improve spontaneously if the respiratory air does not flow through

3) Nasopharyngeal Infections of the New born Infants

The period of the primary occurrence of infections in the nasopharyngeal mucosa of the neonatal infant is a matter of particular interest This region is probably the primary site of air borne infections deep in the organism Simose (1968) in our clinic examined in detail

Table 7 Nasopharyngeal bacterial flora of normal infant.

Micrococcus	72.5%	(87)
Staph. epidermidis	32.5	(39)

+	+	32.8% (19)
+	−	0% (0)
	+	43.1% (25)
	−	24.1% (14)

Arakawa-ku, Tokyo and aged from 6 to 1 years, and the results obtained are given in Table 7

Of the flora detected those with apparent pathogenity are 15.8% staphylococcus aureus, 10.0% streptococcus viridans, 8.3% strept. anhaemolyticus, 5.0% strept. haemolyticus and 2.5 pneumococcus. Staph. epidermidis, together with staph. aureus, was classified, as shown in Table 8, according to the results of coagulase test and fermentation of mannite confirming pathogenecity and, in 32.8% of both strains of staphylococci both tests gave positive results.

From these results it has been amply demonstrated, that the bacterial flora fixed in the nasopharynx of children of various strains of bacteria were detected from each of all 120 children examined and it is characteristic of these strains that gram-positive micrococci, probably a kind of saprophytic organism in the nasopharynx, were found in 72.5% of the subjects.

This fact is interesting to us, as compared with the results of determination of bacterial flora, as shown in Table 9 for the adult nasopharynx. Namely in the nasopharynx of adults the gram-positive micrococci mentioned previously occur only in 14 4% of the cases, in a much smaller percentage than in infants. On the contrary staphylococci are notably growing with age, especially pathogenic staphylococcus

Table 9 Nasopharyngeal bacterial flora in cases of nasopharyngitis.

Staph. epidermidis	45.4%	(98)
Staph. aureus	27.8	(60)
Micrococcus	14.4	(31)

	216 cases	

aureus, from 15 8% in infants to 27.8 in adults. Furthermore, each of the pathogenic organisms of the other strains is also growing in adult cases, which fact may naturally be attributed to their long history

5) **Inflammation of the Nasopharynx with Rise and Fall of its Bacterial Content**

The bacterial infections of the nasopharynx have been mentioned above. However it is natural that the bacterial flora is not always constant. In the case of the so-called "common cold" it will always be accompanied by an acute inflammation of the nasopharynx (I am of the opinion to the contrary that a cold should rather be defined as acute nasopharyngitis.) and the nasopharyngitis develops its local symptoms, which never become evident otherwise subjectively and especially the following symptoms become noticeable (it appears to be fairly well demonstrated that the symptoms in case of cold, such as headache, pyrexia, general feebleness, etc. are closely related with nasopharyngitis as well, and for further details, refer to respective paragraphs on headache and the autonomic nervous system)

1 Feeling of dryness on the dorsal surface of the nasopharynx. (This sensation is frequently complained of erroneously as an abnormal feeling in the pharyngo-laryngeal region.)

2. Open nasal voice (especially of [m n ŋ]) of slight degree, appearing in the earliest stage of a cold.

The nasopharyngitis, therefore, will be felt in the form of an acute exacerbation at least in case of a cold and furthermore, even at the end of the cold inflammation of the nasopharynx is

how the nasopharynx of neonatal infants gets involved with bacterial organisms, and also studied the inflammatory conditions of the nasopharynx of school children and adults.

A total of 100 newborn less than 14 days after birth (of which 86 were aged less than 7 days and thereafter more than 10 cases each respectively) subjects without any noticeable disease of the upper respiratory tract from the neonatal care unit of the maternity room of our university clinic, were examined for the presence of bacterial flora in the nasopharynx. For obtaining material to determine the bacterial flora a sterile cotton swab for nose, with its head bent at an angle of 90° was inserted carefully into the mouth using a tongue depressor to avoid contamination and the dorsal surface of the soft palate was gently scraped material so removed was spread rapidly and if necessary cultured by various cultural methods and studied for the presence of bacterial organisms. The results obtained are given in Table 5

As for the relationship between the lapse of time i.e. days after birth and the detected bacterial flora staphylococcus epidermidis (non pathogenic) for instance was detected in 4 out of 14 cases of the newborn only one day after birth and the positive cases increased with

Table 5 Days after birth and number of cases with positive bacteria.

Days	1	2	3	4	5	6	7	8-14
Staph. epiderm.	4	5	7	9	11	13	6	12
Micrococcus				1		3	3	1
E. coli		1						2

(±)	1
(+)	a few scattered
(++)	moderate disseminated
(+++)	multiple densely packed

the course of time. In regard to the other bacterial organisms (except the cases of gram-positive ones) however they did not always increase in parallel with the days after birth. But the kinds of the detectable bacterial organisms increased gradually. The number of bacterial colonies on a culture plate, as shown in Table 6 is as shown in Fig 3 from Table 5. At a glance it will be found that the number of bacteria adhering to the nasopharynx increases daily.

Even with the superficial examination shown above streptococcus haemolyticus or streptococcus viridans are already found. As already stated an infant which died 12 hours after birth has shown inflammation beginning on the dorsal surface (at the nasal side) of the soft palate and from the nasopharynx of an infant which visited our clinic 10 days after birth with otitis media, pathogenic organisms were found which were similar to those in otitis media. So the infection of the nasopharynx by pathogenic organism occurs earlier than could be expected and therefore the occurrence of the inflammation in the nasopharynx, i.e. nasopharyngitis will presumably take palce shortly after birth.

4) Nasopharyngitis of School Children and Adults

Simosa (1968) studied on the bacterial flora obtained from the nasopharynx in 120 random samples from primary school children living in

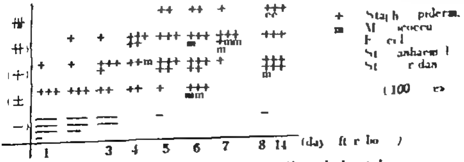

Fig 3. Day after birth and content of bacteria detected

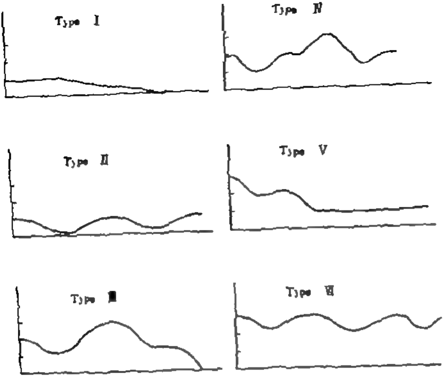

Fig. 4. Bacterial flora curve

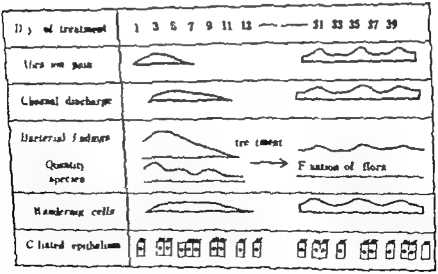

Fig. 5. Bacteriological state and nasopharyngeal findings during local treatment.

revealed by local examination though usually the patient is not conscious of it

The existence of nasopharyngitis as will be mentioned later is to be determined by

1 Amount of exfoliated epithelial cells
2 Appearance of wandering cells,
3 Bacterial content, etc.

In order to compare the bacterial content with the intensity of inflammation however it must be considered, whether or not a method for determination of inflammation exists, irrespective of bacterial content. In our clinic, as will be mentioned later various tests on animals and laboratory tests have revealed the existence of a close relationship between the amount of exfoliated epithelial cells or appearance of wandering cells and the intensity of inflammation and it has been also elucidated that clinically

1 the intensity of pain at and after abrasion of the nasopharyngeal mucosa and

2 the degree of mucosal hemorrhages (the extent of erosion) at and after abrasion

are closely related with the inflammation.

On the strength of these clinical data TANIKAWA has carried out a study of the correlations between the intensity of nasopharyngitis and bacterial flora (The traditional method of study i e. only the visual observation of the color tone (grade of redness) of the mucosa with a posterior rhinoscope etc. is not enough to determine the grade of nasopharyngitis. It can be shown by experiment that the above mentioned criteria such as abrasion pain postabrasive hemorrhages, etc. are much more reliable for this purpose)

TANIKAWA (1970) prepared nasopharyngeal abrasion specimens from patients with nasopharyngitis and normal subjects daily (abrasion culture from the dorsal surface of the soft palate by nasal as well as pharyngeal swabs) and followed the alteration of the bacterial flora in this region This observation was done naturally in parallel with the nasopharyngeal local treatment (application of 1 $ZnCl_2$) however in some cases it was found that the inflammation of the nasopharynx often recurs in spite of therapy In most of these cases, the feeling of dryness in the soft palate the open nasal voice such as found with a cold as mentioned above did not always appear but an acute exacerbation in the nasopharynx, if it ever appeared, almost always ceased within 1–2 days without any subjective symptoms.

The so-called cold therefore should be defined as an acute exacerbation of nasopharyngitis especially with more difinite local symptoms, and accompanied by generalized (acute) symptoms of the autonomic nervous system

By the daily examination of bacterial flora in the nasopharynx it was found that in the nasopharynx with acute symptoms (clinically best judged from the abrasion pain and postabrasive hemorrhages by swabs) regardless of whether the infection is latent or manifest both the quantity and the kind of bacterial organisms are increased

The bacteriological abrasive specimens obtained at the first medical examination from the nasopharynx previous to any treatment contain naturally various kinds of bacteria in large quantities however these organisms react diversely to local treatment (application of 1 $ZnCl_2$) for nasopharyngitis.

In some cases the bacterial flora is rapidly diminished by treatment and the patient recovers from the inflammation while in others the bacterial organisms resist the intensive treatment obstinately and never decrease so that the symptoms cannot improve TANIKAWA classified the clinical course of these bacterial organisms into 6 types as is given in Fig 4

Type I	Slightly alterating bacterial flora with rapid disappearance of bacteria after treatment (15)
Type II	Slightly alterating bacterial flora without disappearance of bacteria (24 %)
Type III	Widely alterating bacterial flora with disappearance of bacteria (11)
Type IV	Widely alterating bacteria flora without disappearance of bacteria (34)
Type V	Widely alterating bacterial flora stabilized after prolonged treatment (5)
Type VI	Many different kinds of bacteria in large quantities without disappearance even after prolonged treatment (1[illegible])

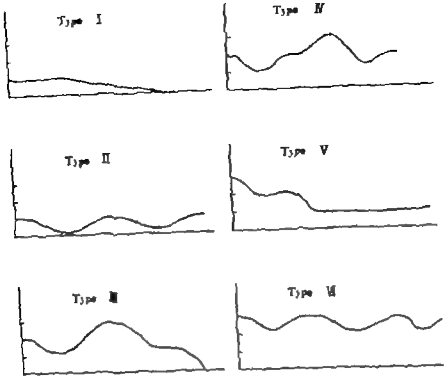

Fig. 4. Bacterial flora curve.

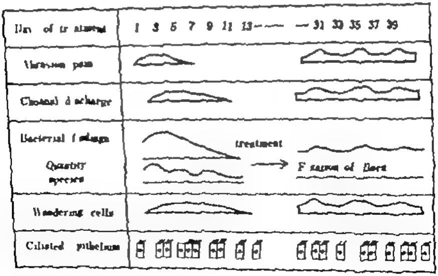

Fig. 5. Bacteriological state and nasopharyngeal findings during local treatment.

During the course of treatment for nasopharyngitis with alterations in the bacterial flora however, staphylococcus aureus is the most fundamental cause of the inflammation

In cases in which the inflammation becomes aggravated therefore staphylococcus aureus naturally increases and other bacteria causing acute inflammations such as streptococcus viridans streptococcus haemolyticus, streptococcus anhaemolyticus, pneumococcus, etc. make their appearance simultaneously In such cases, however only the staphylococcus remains alive generally while the inflammation disappears soon during local treatment. The bacteriological states in these cases are given in Fig 5

The alterations of the bacterial flora however depending also a little upon the techniques of local treatment etc. does not always go parallel with the alterations of the inflammation itself The bacterial flora curve described above should indicate for reference only the average data for the conditions. Further it is characteristic of nasopharyngitis as will be mentioned later that its treatment will also heal dysfunctions of the other distant organs or the whole body

If the inflammation in the nasopharyngeal region as its original point is refractory and persists, however no effects of treatment for the nasopharynx upon the whole body can be expected.

5 Inflammation of the Nasopharynx and Epithelial Changes

In the nasopharynx, as mentioned above latent inflammations exist constantly and recur repeatedly. Thereby it was stated that (1) the nasopharyngeal symptoms are mostly latent in themselves and (2) the diagnosis of these symptoms cannot always be entirely satisfactorily established by traditional oto-rhino-laryngological methods, i.e. visual methods such as pharyngoscopy or posterior rhinoscopy etc. To solve this 2nd diagnostic problem (which is, however, of decided importance in finding the inflammation, called nasopharyngitis) a method must be developed which is entirely different from the traditional ones.

As stated already in the preceding paragraph, abrasion pain, postabrasive hemorrhages, etc. are the clinical criteria for the diagnosis. However in establishing a reliable diagnosis, it is necessary to examine the abrasion specimen from the nasopharyngeal mucosa, because the abrasion pain is a more or less subjective criterion and the hemorrhages can be found only in case of rather severe inflammation with erosion.

In these cases observations of the pathological conditions of bacterial organisms and wandering cells were carried out, and the ciliated epithelium of the nasopharyngeal mucosa was also observed to show marked transformation and desquamation under inflammatory conditions. It has already been found by us at the beginning of the study on nasopharyngitis that in inflammatory conditions numerous epithelial cells are exfoliated and desquamated. Smeared specimens containing the nasopharyngeal epithelium were prepared by slight abrasion of the nasopharyngeal wall (chiefly the dorsal surface of the soft palate) with pharyngeal or nasal swabs and observed easily after Papanicolaou's staining, and the criteria for the correlation between the cytological features of desquamated epithelium and the process of inflammation had to be established. For this purpose the states of improvement and cellular exfoliation were successively recorded in the cases of artificially induced inflammation in the nasopharynx of animals (ISHIKAWA, 1964), the states of improvement and cellular exfoliation were observed during the treatment of nasopharyngitis of man (SAITO, 1963) and the correlations between the abrasion pain or postabrasive hemorrhages and the inflammation were, as mentioned previously, exfoliative-cytologically observed (IDE, 1963a). In our clinic, however, prior to all these methods, MURAKAMI (1967) had performed a morphological study of the exfoliated epithelial cells in cases of nasopharyngitis and made its basis firm.

1) Morphology of the Nasopharyngeal Epithelial Cells

The epithelium of the nasopharynx is ciliated columnar, as has been mentioned. Morphologically this is an epithelium of almost the same type as in the nasal cavities. In the other parts of the pharynx, i.e. meso- and hypopharynx, the epithelium is stratified squamous, and this layer will probably be related downward with the esophageal wall; however, the nasopharyngeal mucosa is characterized only by a pure respiratory type of wall and is entirely different from the pharyngeal mucosa in its morphology.

A normal epithelial cell consists of cilia, cell body, cuticular border, nucleus and tail. According to the results of a morphological study on 100 ciliated epithelial cells obtained from the normal nasopharynx, MURAKAMI (1967) classified them into 4 types as shown in Fig. 6: Type-I, Type II, Type IIIA and Type-IIIB. Type-I, II and III correspond to the medium sized, elongated and shortened cells respectively; subdivision of the type III enables the separation especially of the shortest cells from the others in the same group. The cilia are about 8μ in length and adhere orderly in

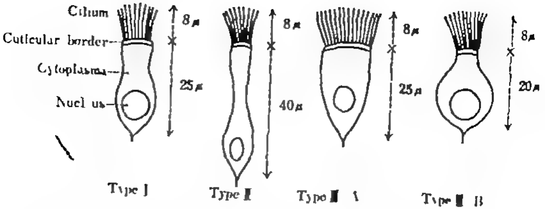

Fig 6. Types of normal ciliated epithelial cells obtained from the normal nasopharynx.

Table 10 Appearance rate of epithelial cells in normal condition.

cell type	ciliar type			
	I	II	III	total
normociliar	66%	8%	6%	80%
incomplet ciliar	4%	2%	1%	7%
aciliar	6%	4%	3%	13%

parallel with each other to the head of each cell In the boundary between its border and the cell body there is a *band shaped darkstaining* region called the cuticular border from which the cilia sprout The normal cilia grow as mentioned above in parallel and in the same length from the entire surface of the cuticular border but occasionally they are shortened frizzled or only half the size of normal ones and they even completely disappear as incomplete forms and the cuticular border which is clearly defined in normal cells becomes ill defined or even lost and invisible occasionally In the smears obtained from the clinically normal appearing nasopharynx the epithelial cells were of the so-called normal type i.e. I II and III as stated above of incompletely ciliated type and non-ciliated type in about 80 7 and 13 of all respectively with a scattering of goblet cells (MURAKAMI 1967)

2) Epithelial Cells in Inflammatory Conditions

Nasopharyngitis exists as stated in the preceding paragraph always latently and presents temporarily local symptoms such as a feeling of dryness on the dorsal surface of the soft palate open nasal voice of slight degree etc especially when having a cold When these transitory local symptoms appear it may be considered as acute nasopharyngitis or acute exacerbation of nasopharyngitis, whereas latent nasopharyngitis in general is to be regarded probably as subacute form of the disease. In the latter cases are included those occasionally in which posterior rhinorrhea is especially marked (even without evidence of sinusitis) but no abrasion pain and hemorrhages are found We regard such a form of the disease as chronic nasopharyngitis. The chronic nasopharyngitis is a *disease refractive* to therapy *In the article* presented by MURAKAMI (1967) the acute nasopharyngitis in this study corresponds to the acute nasopharyngitis as well as the acute exacerbation of chronic nasopharyngitis, and the subacute nasopharyngitis to the non-acute nasopharyngitis without posterior rhinorrhea. The chronic nasopharyngitis corresponds to that with posterior rhinorrhea previously mentioned In these cases however there can be found many cases with marked abrasion pain despite posterior rhinorrhea. Although such classification is, therefore also not always justified we have classified the disease at present into acute subactue and chronic type from 10 years clinical experience

Nasopharyngitis and Desquamation of Epithelium

The correlation between the grade of inflammation and desquamation of the epithelium or transformation of desquamated epithelial cells, as has been mentioned in the preceding paragraph should be stated here in detail There are two ways to observe inflammatory changes in epithelial cells. One is the examination of the desquamated epithelium in the smears from animals with artificially produced acute nasopharyngitis, compared with histopathological

features of the nasopharyngeal mucosa in its respective stage of the disease, and the other is the examination of smears during the recovery course of the patients under treatment. The significance of the desquamated epithelial cells can be exactly determined only by comparison of the results obtained in both these ways.

ICHIKAWA (1964) studied the desquamated epithelial cells of the nasopharynx of rabbits in comparison with the recovery process of an acute inflammation, which was induced by administration of 10% formol in the nasopharynx. This experiment corresponds indeed rather with successive observation of the recovery process of the nasopharyngeal mucosal lesions after instillation of formol, but is interesting in the respect that the possible correspondence of the cytological aspects of desquamated epithelium with the histological features of the mucosa itself within the first 24 hours was noticed, while the desquamated epithelial cells were compared with the mucosal tissue itself during the course 1, 3, 6, 12 and 24 hours and further 3, 7, 14 and 28 days after instillation.

The nasopharyngeal (of the dorsal surface of the soft palate) mucosa of rabbits before instillation of formol is, as shown in Fig. 7a, covered with ciliated epithelium and its smears (Fig. 7b) contain only ciliated epithelial cells. The cilia of the epithelial cells 1 hour after instillation of formol are, as given in Fig. 8a, irregularly concentrated and the intercellular spaces are slightly edematous. The lamina propria shows slight inflammatory edema and cellular infiltra-

parallel with each other to the head of each cell. In the boundary between its border and the cell body there is a band shaped darkstaining region called the cuticular border from which the cilia sprout The normal cilia grow as mentioned above in parallel and in the same length from the entire surface of the cuticular border but occasionally they are shortened frizzled or only half the size of normal ones and they even completely disappear as incomplete forms and the cuticular border which is clearly defined in normal cells, becomes ill defined or even lost and invisible occasionally In the smears obtained from the clinically normal appearing nasopharynx, the epithelial cells were of the so-called normal type i e I II and III as stated above of incompletely ciliated type and non-ciliated type in about 80 7 and 13 of all respectively with a scattering of goblet cells (Murakami 1967)

2) Epithelial Cells in Inflammatory Conditions

Nasopharyngitis exists as stated in the preceding paragraph always latently and presents temporarily local symptoms such as a feeling of dryness on the dorsal surface of the soft palate open nasal voice of slight degree etc. especially when having a cold When these transitory local symptoms appear it may be considered as acute nasopharyngitis or acute exacerbation of nasopharyngitis whereas latent nasopharyngitis in general is to be regarded probably as subacute form of the disease In the latter cases are included those occasionally in which posterior rhinorrhea is especially marked (even without evidence of sinusitis) but no abrasion pain and hemorrhages are found. We regard such a form of the disease as chronic nasopharyngitis. The chronic nasopharyngitis is a disease refractive to therapy In the article presented by Murakami (1967) the acute nasopharyngitis in this study corresponds to the acute nasopharyngitis as well as the acute exacerbation of chronic nasopharyngitis, and the subacute nasopharyngitis to the non-acute nasopharyngitis without posterior rhinorrhea The chronic nasopharyngitis corresponds to that with posterior rhinorrhea previously mentioned In these cases, however there can be found many cases with marked abrasion pain despite posterior rhinorrhea. Although such classification is, therefore also not always justified we have classified the disease at present into acute subactue and chronic type from 10 years clinical experience.

Nasopharyngitis and Desquamation of Epithelium

The correlation between the grade of inflammation and desquamation of the epithelium or transformation of desquamated epithelial cells as has been mentioned in the preceding paragraph should be stated here in detail There are two ways to observe inflammatory changes in epithelial cells. One is the examination of the desquamated epithelium in the smears from animals with artificially produced acute nasopharyngitis, compared with histopathological

features of the nasopharyngeal mucosa in its respective stage of the disease, and the other is the examination of smears during the recovery course of the patients under treatment. The significance of the desquamated epithelial cells can be exactly determined only by comparison of the results obtained in both these ways.

ISHIKAWA (1964) studied the desquamated epithelial cells of the nasopharynx of rabbits in comparison with the recovery process of the acute inflammation, which was induced by administration of 10% formol in the nasopharynx. This experiment corresponds indeed rather with a successive observation of the recovery process of the nasopharyngeal mucosal lesions after instillation of formol, but is interesting in the respect that the possible correspondence of the cytological aspects of desquamated epithelium with the histological features of the mucosa itself within the first 24 hours was noticed while the desquamated epithelial cells were compared with the mucosal tissue itself during the course 1, 3, 6, 12 and 24 hours and further 3, 7, 14 and 28 days after instillation.

The nasopharyngeal (of the dorsal surface of the soft palate) mucosa of rabbits before instillation of formol is, as shown in Fig. 7a, covered with ciliated epithelium and its smears (Fig. 7b) contain only ciliated epithelial cells. The cilia of the epithelial cells 1 hour after instillation of formol are, as given in Fig. 8a, irregularly concentrated and the intercellular spaces are slightly edematous. The lamina propria shows slight inflammatory edema and cellular infiltra-

parallel with each other to the head of each cell. In the boundary between its border and the cell body there is a band shaped darkstaining region called the cuticular border from which the cilia sprout The normal cilia grow as mentioned above in parallel and in the same length from the entire surface of the cuticular border but occasionally they are shortened frizzled or only half the size of normal ones and they even completely disappear as incomplete forms and the cuticular border which is clearly defined in normal cells, becomes ill defined or even lost and invisible occasionally In the smears obtained from the clinically normal appearing nasopharynx, the epithelial cells were of the so-called normal type i e. I II and III as stated above, of incompletely ciliated type and non-ciliated type in about 80, 7 and 13 of all respectively with a scattering of goblet cells (Murakami 1967)

2) Epithelial Cells in Inflammatory Conditions

Nasopharyngitis exists, as stated in the preceding paragraph always latently and presents temporarily local symptoms such as a feeling of dryness on the dorsal surface of the soft palate, open nasal voice of slight degree etc. especially when having a cold When these transitory local symptoms appear it may be considered as acute nasopharyngitis or acute exacerbation of nasopharyngitis whereas latent nasopharyngitis in general is to be regarded probably as subacute form of the disease In the latter cases are included those occasionally in which posterior rhinorrhea is especially marked (even without evidence of sinusitis) but no abrasion pain and hemorrhages are found. We regard such a form of the disease as chronic nasopharyngitis. The chronic nasopharyngitis is a disease refractive to therapy In the article presented by Murakami (1967) the acute nasopharyngitis in this study corresponds to the acute nasopharyngitis as well as the acute exacerbation of chronic nasopharyngitis and the subacute nasopharyngitis to the non acute nasopharyngitis without posterior rhinorrhea. The chronic nasopharyngitis corresponds to that with posterior rhinorrhea previously mentioned In these cases, however there can be found many cases with marked abrasion pain despite posterior rhinorrhea. Although such classification is, therefore, also not always justified we have classified the disease at present into acute subactue and chronic type from 10 years clinical experience

Nasopharyngitis and Desquamation of Epithelium

The correlation between the grade of inflammation and desquamation of the epithelium or transformation of desquamated epithelial cells, as has been mentioned in the preceding paragraph should be stated here in detail There are two ways to observe inflammatory changes in epithelial cells. One is the examination of the desquamated epithelium in the smears from animals with artificially produced acute nasopharyngitis, compared with histopathological

features of the nasopharyngeal mucosa in its respective stage of the disease, and the other is the examination of smears during the recovery course of the patients under treatment. The significance of the desquamated epithelial cells can be exactly determined only by comparison of the results obtained in both these ways.

ICHIKAWA (1964) studied the desquamated epithelial cells of the nasopharynx of rabbits in comparison with the recovery process of its acute inflammation, which was induced by administration of 10% formol in the nasopharynx. This experiment corresponds indeed rather with successive observation of the recovery process of the nasopharyngeal mucosal lesions after instillation of formol but is interesting in the respect that the possible correspondence of the cytological aspects of desquamated epithelium with the histological features of the mucosa itself within the first 24 hours was noticed, while the desquamated epithelial cells were compared with the mucosal tissue itself during the course 1, 3, 6, 12 and 24 hours and further 3, 7, 14 and 28 days after instillation.

The nasopharyngeal (of the dorsal surface of the soft palate) mucosa of rabbits before instillation of formol is, as shown in Fig. 7a, covered with ciliated epithelium and its smears (Fig. 7b) contain only ciliated epithelial cells. The cilia of the epithelial cells 1 hour after instillation of formol are, as given in Fig. 8a, irregularly concentrated and the intercellular spaces are slightly edematous. The lamina propria shows slight inflammatory edema and cellular infiltra-

incomplete ciliar	4	2%	1	7%
aciliar	6	4%	3	13%

parallel with each other to the head of each cell. In the boundary between its border and the cell body there is a band-shaped darkstaining region called the cuticular border from which the cilia sprout. The normal cilia grow as mentioned above in parallel and in the same length from the entire surface of the cuticular border but occasionally they are shortened frizzled or only half the size of normal ones and they even completely disappear as incomplete forms and the cuticular border which is clearly defined in normal cells, becomes ill defined or even lost and invisible occasionally In the smears obtained from the clinically normal appearing nasopharynx the epithelial cells were of the so-called normal type i e I II and III as stated above of incompletely ciliated type and non-ciliated type in about 80 7 and 13 of all respectively with a scattering of goblet cells (MURAKAMI 1967)

2) **Epithelial Cells in Inflammatory Conditions**

Nasopharyngitis exists, as stated in the preceding paragraph always latently and presents temporarily local symptoms such as a feeling of dryness on the dorsal surface of the soft palate open nasal voice of slight degree etc especially when having a cold. When these transitory local symptoms appear it may be considered as acute nasopharyngitis or acute exacerbation of nasopharyngitis, whereas *latent nasopharyngitis* in general is to be regarded probably as subacute form of the disease. In the latter cases are included those occasionally in which posterior rhinorrhea is especially marked (even without evidence of sinusitis) but no abrasion pain and hemorrhages are found. We regard such a form of the disease as chronic nasopharyngitis. The chronic nasopharyngitis is a disease refractive to therapy In the article presented by MURAKAMI (1967) the acute nasopharyngitis in this study corresponds to the acute nasopharyngitis as well as the acute exacerbation of chronic nasopharyngitis, and the subacute nasopharyngitis to the non-acute nasopharyngitis without posterior rhinorrhea. The chronic nasopharyngitis corresponds to that with posterior rhinorrhea previously mentioned In these cases however there can be found many cases with marked abrasion pain despite posterior rhinorrhea. Although such classification is, therefore also not always justified we have classified the disease at present into acute subactue and chronic type from 10 years clinical experience

Nasopharyngitis and Desquamation of Epithelium

The correlation between the grade of inflammation and desquamation of the epithelium or transformation of desquamated epithelial cells as has been mentioned in the preceding paragraph should be stated here in detail There are two ways to observe inflammatory changes in epithelial cells. One is the examination of the desquamated epithelium in the smears from animals with artificially produced acute nasopharyngitis, compared with histopathological

b.
The cells are normal in the shape

Fig 15. 28 days after instillation.

tion, and in the corresponding smears, as shown in Fig 8b the cilia are found in irregular bundles and the cells contain multiple vacuoles of varying size in the cytoplasm The epithelial cells then become easily desquamated The intercellular edema becomes marked three hours after instillation (Fig 9a) the epithelial cells are partly desquamated and leucocytic emigration through the loosening epithelial layer is found In the smears as seen in Fig 9b the epithelial cells become desquamated much more easily and the transformation of cells swelling and vacuolization of cytoplasma are conspicuous

Six hours later (Fig 10a) the epithelial layer is necrotized almost completely and only a few reserve cells are visible on the basement membrane In the lamina propria dilatation of blood vessels edema and cell infiltration are noted In the smears (Fig 10b) transformation and degeneration of the epithelial cells become conspicuous and irregularity of cilia loosening of cytoplasma swelling of nucleus, karyolysis etc are noted

In the histology 24 hours after instillation (Fig 11a) the normal structure of the epithelial layer disappears completely undergoes necrosis and single-layered reserve cells with pyknosis are found along the basement membrane In the smears (Fig 11b) the cytoplasma of the epithelial cells is destroyed and lost and only a few round or oval nuclei are scattered here and there

In the cases 3 days after instillation as seen in the histology (Fig 12a) the so-called ciliated epithelium of the mucosa disappeared completely and the mucosal surface was, though somewhat eroded more or less recovered with a little less prominent infiltration of neutrophiles than before (i e. 24 hours later) In this period a beginning regeneration of epithelial cells is observed which are at first round in shape and of the basal cell type The epithelial layer increases day after day gradually in its thickness and on the 7th day it becomes 1 5 cells thick, while each cell is round or cylindrical in its shape but cilia are not yet found In this stage the infiltration of the neutrophiles is at its minimum (Fig 13a) and the obtained smears contain only the rounded epithelial cells (Fig 13b)

On the 14th day after instillation the cilia are already grown but only incompletely from the more or less plump cell body (Fig 14a)

On the 28th day the regeneration of the mucosal epithelium is perfect the ciliated cells are well formed the cilia and all other parts of the cell are completed (Fig 15a b)

In Fig 16 the above course is shown in a diagrammatic way The epithelial desquamation due to formol instillation becomes suddenly marked after instillation reaches a maximum in 3 hours, passes through a minimum in 24 hours and thereafter gradually increases while the wandering cells such as leucocytes t delay more or less in appearance reach a maximum

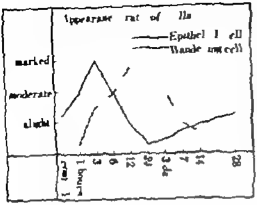

Fig. 18.

in 24 hours and then gradually decrease.

The correlations between the changes of the nasopharyngeal mucosa of rabbits with induced acute inflammation, especially the regenerating process of its epithelium and the cytological features in the smears are as given above. These correlations may suggest, in comparison with the nasopharyngeal smears of man, especially in the recovery stage during the treatment for nasopharyngitis, the true states of the inflammation called nasopharyngitis.

3) Epithelial Changes during the Course of Local Treatment of Nasopharyngitis

It is stated above that the nasopharyngeal mucosal epithelium varies morphologically over a wide range and that its changes are related especially to the intensity of inflammation. In this paragraph the changes of epithelial features *during the local therapy of nasopharyngitis* will be referred to.

The treatment of nasopharyngitis consists generally in applying 1 % zinc chloride solution (with a little local anesthetic added) to the entire mucosal surface of the nasopharynx through the pharynx (with pharyngeal swabs) and through the nose (with nasal swabs) however severe pain is caused by frequent application and considerable hemorrhage from the mucosal surface is observed occasionally after application. In some cases the application may cause only a little pain and no hemorrhage and the cytological features of smears in such cases differ distinctly from those in cases with severe pain or hemorrhage. In the former cases the epithelium is markedly desquamated and so transformed that it is swollen with indistinct structure, *missing cuticular* borders, lacking cilia, etc. whereas in the latter cases the desquamated epithelial cells are scarce, normally elongated in their shape, and the cellular structure cilia, cuticular border etc. remain perfect.

In the cases with nasopharyngeal hemorrhage and severe pain at and after abrasion desquamation and transformation of the epithelial cells is much more conspicuous. Moreover in *such cases with marked epithelial desquamation and transformation numerous bacteria are apt to appear associated* with an emigration of wandering cells such as neutrophile leucocytes, etc. however in the latter cases, i.e. those without noticeable pain due to abrasion, the bacterial organisms are so inconspicuous quantitatively as well as qualitatively that they are not easily found. There are scarcely any wandering bacteria to be found. *From these findings it* may be said that nasopharyngeal pain or hemorrhages due to mucosal abrasion suggest the presence of inflammation in this part of the body. As stated above, nasopharyngeal pain or hemorrhages at abrasion correspond with the three outstanding cytological features in the smears obtained from the mucosa, i.e. epithelial desquamation, appearance of wandering cells and increase of bacterial organisms, so the correlations between these two components were studied in further detail.

Correlation between Abrasion Pain and the Degree of Exfoliation.

The mucosal abrasion of the inflamed nasopharynx with swabs causes severe pain and often hemorrhages. This abrasion pain was classed provisionally in 3 grades, i.e. marked~moderate (卌~卄) slight (+) and very slight~no pain (±~−) while the respective numbers of ciliated epithelial cells exfoliated in the smears in each microscopic field (×100) were classed as very marked~numerous, passing through marked, moderate, slight and finally very slight~less than 10, and the correlations between both these components were studied on both sides separately.

As evidenced in Table 11 in cases with

Table 11 Relation between abrasion pain and exfoliation degree of ciliated epithlial cells (320 sides)

exfoliation	abrasion pain		
	+++~++	+	±~−
extrem marked	3	1	0
marked	40	21	8
moderate	28	47	25
slight	17	52	24

Table 13 Relation between transformation degree of ciliated epithelial cells and quantity of leukocytes (314 sides)

leukocytes	deform.		
	marked	moderate	slight normal
+++	11	12	
++	15	25	26
+	10	49	68
normal	9	19	68
total	45	103	164

abrasion pain +++~++ + and ±~− the exfoliation degree is marked (40 cases) slight (52 cases) and very slight (27 cases) respectively It may be said therefore that the degree of nasopharyngeal abrasion pain varies almost in parallel with the exfoliation degree of ciliated epithelial cells.

Correlation between the Degree of Exfoliation and Transformation of Ciliated Epithelium

The frequency of appearance of the ciliated cells was graded as in the preceding paragraph and the cellular transformation was clases as 1) marked almost aciliated ill-defined poorly stained cells with markedly swollen cytoplasma and similar to Type-III in their shape passing through 2) moderate 3) slight and 4) normal type i e. in 4 grades Six cases were excluded in which most of the ciliated epithelial cells had not been exfoliated In cases with very slight exfoliation as given in Table 12 the transformation was slight~normal in 28 cases, i e it shows the high percentage of 69 % But in cases with slight moderate, and marked exfoliation, the transformation was mostly moderate and marked exfoliation the transformation was mostly moderate in 37 cases, i e 39 4 slight in 47 cases, i e 47 0 and slight in 35 cases i e. 50 7% respectively So there is no definite correlation between the two components except in cases with very slight exfoliation Contrary to the fact of the parallel course of abrasion pain with that of exfoliation, the transformation of the epithelial cell does not necessarily go parallel with its exfoliation.

Table 12 Relation between exfoliation degree of ciliated epithelial cells and their transformation degree (314 sides)

transformation	exfol.				
	extrem. marked	marked	moderat	slight	very slight

moderate		25	32	37	10
slight	1	35	47	27	14
none	1	3	7	13	14
total	4	69	100	94	47

Correlation between the Degree of Exfoliation of Ciliated Epithelium and the Leucocytes Appearing in the Smears

The appearance of leucocytes and lymphocytes was classed as marked (+++) numerous, having an even distribution in the smears, passing through moderate (++) slight (+) and normal as shown in Table 13 In the cases with marked moderate and slight~normal transformation the appearance of leucocytes was mostly ++~+++ in 26 (26/45=57 8 %) +~++ in 74 (74/103=70 5 %) and normal −~+ in 136 cases (136/164=82 9) respectively In other words leucocytes appeared in the overwhelming majority of cases. In cases with marked moderate and slight transformation the appearance of leucocytes was mostly ++ in 15 + in 49 and + or normal in 68 cases therefore the transformation of the epithelial cells appears more or less to parallel the appearance of leucocytes In short the exfoliation of the epithelial cells due to nasopharyngeal abrasion runs relatively parallel to the local pain at abrasion and also somewhat parallel to the regional appearance of leucocytes whereas the degree of exfoliation and that of the transformation of exfoliated cells do not particularly parallel each other Clinical experience indicates that the abrasion of the regional mucosa of the nasopharynx with acute or subacute inflammation causes pain proportional to the in

tensity of inflammation, and furthermore hemorrhages are frequently found after abrasion. This will be elucidated by observation of the inflammation in its recovery process under local treatment.

Microscopic observation of the smears obtained from the nasopharyngeal mucosa with severe abrasion pain reveals, therefore, desquamation of epithelial cells, proliferation of bacteria and emigration of leucocytes, which *are increased with the severity of abrasion pain.* The cytological findings of the smears, such as epithelial desquamation, bacterial flora and leucocytic emigration improve as the abrasion pain or hemorrhages gradually decrease during local treatment for nasopharyngitis, and finally are normalized with disappearance of abrasion pain and hemorrhages, namely the epithelial desquamation diminishes and the bacteria as well as leucocytes disappear. The above mentioned studies go into further details of such *clinical findings and reveal that the epithelial* desquamation found in the smears runs parallel to the local abrasion pain. Incidentally the abrasion pain of the nasopharynx increases, as mentioned previously, almost in direct proportion to the intensity of inflammation and changes generally in parallel to cytological features of the smears. *However marked epithelial* desquamation and appearance of bacteria as well as wandering cells are to be found in some cases without noticeable abrasion pain. In such cases the desquamated epithelial cells are often transformed and associated also with the appearance of leucocytes, goblet cells, etc. Clinically the patients complain of a posterior rhinorrhea (despite absence of sinusitis) and the disease is often refractory to local treatment. Nasopharyngitis of this type is designated chronic nasopharyngitis by the author, whereas that with severe abrasion pain is referred to as subacute nasopharyngitis.

Acute nasopharyngitis corresponds to an acute stage of subacute nasopharyngitis with repeated relapse and especially with visible symptoms, i.e., a feeling of dryness on the dorsal surface of the soft palate and a slightly open nasal voice, the so-called "grippe voice". This acute nasopharyngitis is the so-called cold and the symptoms appearing in case of a cold, such as headache, fever, general feebleness, etc. can be connected with subacute nasopharyngitis, as will be mentioned in the following. When treatment is given for acute nasopharyngitis from this viewpoint, a cold is observed to disappear very soon thereafter.

none	1	3	7	13	14
total	4	69	100	94	47

Correlation between the Degree of Exfoliation of Ciliated Epithelium and the Leucocytes Appearing in the Smears

The appearance of leucocytes and lymphocytes was classed as marked (⧻) numerous, having an even distribution in the smears, passing through moderate (⧺) slight (+) and normal as shown in Table 13 In the cases with marked moderate and slight~normal transformation the appearance of leucocytes was mostly ⧺~⧻ in 26 (26/45 = 57 8) +~⧺ in 74 (74/105 = 70.5) and normal −~+ in 136 cases (136/164 = 82 9) respectively In other words leucocytes appeared in the overwhelming majority of cases. In cases with marked moderate and slight transformation the appearance of leucocytes was mostly ⧺ in 15, + in 49 and + or normal in 68 cases therefore the transforma tion of the epithelial cells appears more or less to parallel the appearance of leucocytes. In short the exfoliation of the epithelial cells due to nasopharyngeal abrasion runs relatively parallel to the local pain at abrasion and also somewhat parallel to the regional appearance of leucocytes, whereas the degree of exfoliation and that of the transformation of exfoliated cells do not particularly parallel each other Clinical experience indicates that the abrasion of the regional mucosa of the nasopharynx with acute or subacute inflammation causes pain proportional to the in

tensity of inflammation, and furthermore hemorrhages are frequently found after abrasion. This will be elucidated by observation of the inflammation in its recovery process under local treatment.

Microscopic observation of the smears obtained from the nasopharyngeal mucosa with severe abrasion pain reveals, therefore, desquamation of epithelial cells, proliferation of bacteria and emigration of leucocytes, which are increased with the severity of abrasion pain. The cytological findings of the smears, such as epithelial desquamation, bacterial flora and leucocytic emigration improve as the abrasion pain or hemorrhages gradually decrease during local treatment for nasopharyngitis, and finally are normalized with disappearance of abrasion pain and hemorrhages, namely the epithelial desquamation diminishes and the bacteria as well as leucocytes disappear. The above mentioned studies go into further details of such clinical findings and reveal that the epithelial desquamation found in the smears runs parallel to the local abrasion pain. Incidentally, the abrasion pain of the nasopharynx increases, as mentioned previously, almost in direct proportion to the intensity of inflammation and changes generally in parallel to cytological features of the smears; however, marked epithelial desquamation and appearance of bacteria as well as wandering cells are to be found in some cases without noticeable abrasion pain. In such cases the desquamated epithelial cells are often transformed and associated also with the appearance of leucocytes, goblet cells, etc. Clinically the patients complain of a posterior rhinorrhea (despite absence of sinusitis) and the disease is often refractory to local treatment. Nasopharyngitis of this type is designated chronic nasopharyngitis by the author, whereas that with severe abrasion pain is referred to as subacute nasopharyngitis.

Acute nasopharyngitis corresponds to an acute stage of subacute nasopharyngitis with repeated relapse and especially with notable symptoms, i.e. a feeling of dryness on the dorsal surface of the soft palate and a slightly open nasal voice, the so-called "grippe-voice". This acute nasopharyngitis is the so-called cold and the symptoms appearing in case of a cold, such as headache, fever, general feebleness, etc. can be connected with subacute nasopharyngitis, as will be mentioned in the following. When treatment is given for acute nasopharyngitis from this viewpoint, a cold is observed to disappear very soon thereafter.

6 Pathogenesis of Nasopharyngitis

Nasopharyngitis occurs at first as a reactive inflammation with physical and chemical actions caused by atmospheric dust particles attached to the nasopharyngeal wall which were drawn in with the air through the nasal cavities. Such an incipient inflammation is naturally of such a slight degree, that it is probably invisible and is essentially a reversible process unless the stimuli are repeated. Although this inflammation will disappear if the causal stimuli are removed still this reversibility of the inflammation is unlikely for the following reasons

1) The air cannot be absolutely clear and the nasopharyngeal irritation by dust particles occurs without interruption

2) This irritation is due not only to the physical action of dust particles, but also to the chemical stimuli of their soluble elements or gaseous substances, e.g. sulfur dioxide.

3) Once an inflammation is initiated by primary irritation the subsequent stimuli cause a much more intense reaction than the previous time

4) The bacteria on the dust particles attach to the nasopharyngeal wall and if inflammation exists and the bacteria are well adapted to the environment proliferate further and the proliferation itself makes the inflammation worse

5) Some of the bacterial flora after they have once contaminated and connected themselves with an inflammation preserve always their minimum life wheather they repeat more or less alteration according to that of environment. They survive further as weeds grow and may play a significant role in aggravation of th inflammation while they recover themselves under favourable circumstances. The bacteria causing chronic inflammations in these ways are staphylococcus aureus, pseudomonas aeruginosa and proteus the so-called Gram negative bacilli

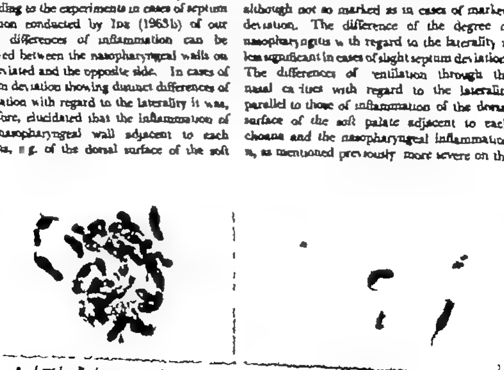
6) In the case of acute exacerbation of the inflammation the above mentioned bacteria increase markedly hemolytic streptococci, pneumococci etc. make their appearance again, and pseudomonas aeruginosa is occasionally found. These bacterial organisms disappear or become markedly weak, when the acute stage of the inflammation has passed

7) Inflammatory foci in the nasopharynx, once developed and fixed, chagne according to the general conditions. In cases for instance, of a cold the nasopharyngitis recurs acutely The author is of the opinion that the opportunity for this recurrence should be regarded as a sort of conditioned reflex resulting from inflammatory foci with acute exacerbation which has become chronic due to certain alterations in physical conditions.

8) The word conditioned reflex may sound strange but in understanding the process of inflammation it is convenient to imagine a reflex process e.g. a reflex under certain conditions via the autonomic nervous system and resulting for instance in salivation. For this purpose experimental studies are of course required but they have not been made at present. By observation of the nasopharynx in case of a cold the presence of an extensive acute inflammation in the nasopharynx is always ascertained. Nasopharyngitis in its latent stage of inflammation has very significant effects on the autonomic nervous system of the whole body and the autonomic nerves in the case of a marked inflammation become, as our experiments indicated hypersensitive and such a hypersensitivity is, as is also demonstrated restored to normal by treatment of the nasopharynx. Since the nasopharyngitis associated with a cold, however always develops severe (mostly local) symptoms, the general symptoms of a cold are to be regarded as referable to acute nasopharyngitis. In the case of a cold caused as mentioned previously by chilling as a dynamic stimulus (e.g. abrupt fall of temperature

etc.) these dynamic changes of temperature lead to an acute inflammation (relapse) of the nasopharynx. This means a relation between *nasopharyngitis* and changes in temperature and le da us to advance the hypothesis that changes in temperature cause an acute exacerbation of persistent nasopharyngitis. *The* correlations between these two components appeared to be a phenomenon like a conditioned reflex. That is, certain chronic inflammatory foci may for instance, progress into the acute stage under a certain physical condition. One of the experiments designed by me consists in leading the chronic inflammation, if possible, into an acute stage by chilling using animals with induced chronic inflammatory foci which are conditioned *to become acute with simultaneous* partial chilling of the body and corresponding stimulation of the inflammatory foci.

9) Differences of ventilation with regard to the laterality of the nasal cavity also controls over the inflammations of the nasopharynx. According to the experiments in cases of septum deviation conducted by Ino (1963b) of our clinic, differences of inflammation can be observed between the nasopharyngeal walls on the deviated and the opposite side. In cases of septum deviation showing distinct differences of ventilation with regard to the laterality it was, therefore, elucidated that the inflammation of the nasopharyngeal wall adjacent to each choana, e.g. of the dorsal surface of the soft palate differs significantly in its intensity with regard to the laterality. A comparative examination of the smears prepared separately from the mucosa of the dorsal *surface of the* soft palate adjacent to the choanae with nasal swabs introduced through bilateral nasal cavities *separately into the nasopharynx reveals* that the inflammation of the mucosa *shows a* higher degree of activity on the deviated side than on the opposite side (Figs. 17–19). The more obvious the septum deviation, the more significant *this difference of activity* becomes. According to the model experiment made by Ino, it has become clear that the adhesion of dust particles to *the nasopharyngeal wall is* especially marked on the deviated side in the case of *remarkable septum deviation. In Table 14, 15* and 16 are given the differences of (subjective) nasal obstruction on the deviated side, the more severe is the inflammation of the nasal mucosa on the occluded side. This tendency is to be found also in cases fo moderate deviation, although not so marked as in cases of marked deviation. The difference of the degree of nasopharyngitis with regard to the laterality is less significant in cases of slight septum deviation. The differences of ventilation through the nasal cavities with regard to the laterality parallel to those of inflammation of the dorsal *surface of the* soft palate adjacent to each *choana and the* nasopharyngeal inflammation is, as mentioned previously, more severe on the



a. Case 1. Region to convex side of the patient with severe deviation.
Great number of exfoliation of ciliated epithelial cells, partial swelling of cytoplasm, Acudinum are seen.

b. Region to concave side of the same patient.
Comparatively normal ciliated epithelial cells; cilia are seen.

Fig. 17 Epithelial smeargrams of nasopharyngeal mucosa to convex and concave side of nasal septum.

a. Case 3 Region to convex side of the patient with severe deviation
Swelling of the cytoplasm in many of the epithelial cells, deformation and poor staining are remarkable Little cilia and striated borders are perceived. Leukocytes and lymphocytes are mingled.

b. Region to concave side of the same patient.
Small number of goblet cells are mingled with ciliated epithelial cells Type III A part of the epithelial cells is swollen and vacuolated together with the disappearance of cilia and striated borders.

Fig 18.

a. Case 5 Region to convex side of the patient with less severe deviation
Many ciliated epithelial cells are exfoliated Deformation is not so remarkable Striated borders and cilia are seen.

b. Region to concave side of the same patient.
Ciliated epithelial cells with almost normal cilia.

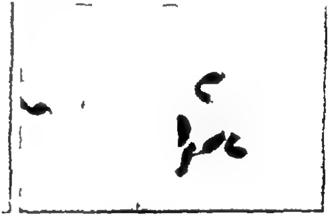
deviated, i.e. narrowed side. *The reason is that* the inflammation was further intensified by *dust collecting in a part of the nasopharynx* adjacent to the choana like a drift, where the air inhaled separately through bilateral nostrils flow with less energy on the side with less ventilation than the opposit side. The marked inflammation caused in this w y also causes an aggravation of the inflammatory changes in the adjacent tissue, and constitutes a factor contributing toward aggra ation of the inflammation *of the entire nasopharynx. This is the* reason why so-called i tranasal orthopedic *treatment symmetrizing bilateral ventilation is* regarded as an important element in cases of nasopharyngitis. Although the intranasal-orthopedists have hitherto stated very bstract edly functional improvement of the body by regulating the air passages " yet it can readily be explained by *introducing* such a concept in their viewpoint, as the localization of nasopharyngitis owing to the difference of ventilation with regard to the laterality because *of the* septum deviation, etc. as mentioned above. In other words, *irregularity of the intranasal air flow—nasopharyngitis—various kinds of general disease resulting from naso*pharyngitis.

a. Case 3: Region to con ex side of the patient w th severe deviation.
Swelling of the cytoplasm in ma y of the epithelial cells, deformation and poor staining are remarkable. Little cilia and striated borders are percei ed. Leukocytes and lymphocytes re mingled.

b. Region t concave side of the same patient.
Small number of goblet cells are mingled w th ciliated epithelial cells Type III A part of the epithelial cells is swollen and vacuolated together with th disappearance of cilia and triated borders.

Fig 18.

a. Case 5 Region to con ex side of the patient w th less sever deviation
Ma y ciliated epithelial cells are exfoliated. Deformation is not so remarkable Striated borders and cilia are seen.



b. Region to conca side of the same patient.
Ciliated epithelial cells w th almost normal cilia.

strate the presence of erosion on the mucosal surface.

The pain during and after abrasion of the nasopharyngeal mucosa with local hemorrhages establishes proof of the presence of inflammations, especially of acute or subacute ones. This fact will be confirmed by clinical course of the ailment and by the transition of smears from mucosal abrasion specimens observed successively during the course. The previously mentioned abrasion pain or post-brush hemorrhages, as stated already parallel the severity of inflammation found in the smears. When hemorrhages or pain during treatment is gradually reduced only by nasopharyngeal local treatment (daily application of 1% $ZnCl_2$) the cytological findings of the smears will be, in accordance with the treatment, gradually improved and finally in the smears from the nasopharyngeal mucosa will be lacking entirely in abrasion pain and hemorrhages, desquamated epithelial cells will be scarce, wandering cells will disappear completely and bacterial content will also be decreased markedly.

In regard to the nasopharynx, in short, inflammations are originally present, so its normal aspect does not appear till these inflammations are cured. Cases in which almost normal smears can be obtained unless treated from beginning are seldom, if ever to be found. According to our investigation moderate inflammation was found in 69.8% of 202 schoolchildren examined and marked nasopharyngitis was, as will be mentioned later found in about 80% of 4 000 out-patients.

The findings in cases with severe inflammation are given in the following in comparison with those in almost healed cases.

Findings	Nasopharyngitis marked	slight
Epithelium	Desquamation & Deformation, marked	Normal Epithelial Cells
Wandering Cells	present	(−)
Bacterial Content	increased in number and kind	very low
Abrasion Pain	(#)	(±)~(−)
Postabrasion Hemorrhage	(#)~(+)	(−)

The local diagnosis of nasopharyngitis is, in consideration of these results, to be made as follows

1. *Abrasion pain in the nasopharyngeal mucosa caused by swabs.*
2. Hemorrhages during abrasion of the nasopharyngeal mucosa caused by swabs (only in cases of marked inflammation with erosion)
3. Smears of nasopharyngeal abrasion specimens (smears prepared with abrasion swabs)
   i. Desquamated epithelium Papanicolaou Staining
   ii. Wandering cells Giemsa Staining
   iii. *Bacteria Culture identification, oil immersion*

Furthermore, the posterior rhinoscopic and nasopharyngoscopic findings are also to be referred to. Nasopharyngitis exists always or almost always regardless of the presence or absence of inflammations of adjacent organs, so that even the absence of inflammations of adjacent organs, e.g. of tonsillitis or pharyngitis, does not afford conclusive evidence against the presence of nasopharyngitis.

7 Diagnosis of Nasopharyngitis

Concerning the disease called nasopharyngitis, little has been discussed up to this time in medical science The existence of such an inflammation is however quite possible and can actually be demonstrated in a great many subjects. Nevertheless this has not been made the subject of medical studies for many reasons such as the following

1 Nasopharyngitis is mostly latent without local symptoms and there are rarely subjective complaints.

2 The nasopharynx is a structure which light can hardly reach. Accordingly the presence of slight nasopharyngeal lesions such as simple inflammation cannot always be determined by conventional optical methods.

As a local sign of nasopharyngitis in its acute onset there can be found a feeling of dryness in the base of nasopharynx i e. on the dorsal surface of the soft palate. This sign corresponds with an abnormal feeling in the soft palate mostly encountered in early stages of a cold and with an open nasal voice called grippe vioce (a kind of nasal voice, entirely different from the closed nasal voice which is due to nasal obstruction owing to a cold accompanied by rhinitis) This feeling of abnormality of dryness appearing on the dorsal surface of the soft palat often spreads, however into the throat or pharyngolaryngological region. In many cases it is complained of as an abnormal feeling in the throat region and it is natural that the physician is apt to investigate only the findings of the mesopharynx or larynx and diagnoses as pharyngitis laryngitis or sometimes as a nervous complaint showing no change in the throat In such cases, however the origin of the bad feeling in throat can easily and clearly be discovered by swabbing the nasopharynx

The existence of pharyngitis or laryngitis must not be neglected The diagnosis of these diseases can be carried out as follows local hyperemia and pain when swallowing (especially on one side of pharynx) in pharyngitis, hoarseness and vocal cord hyperemia in laryngitis) But even in these cases the complication of nasopharyngitis is always present and the direct treatment of this nasopharyngitis will make the progress of the original inflammation better

Furthermore this abnormal feeling in the soft palate or the open nasal voice appears for the most part exclusively in the early stages of a cold and disappears within 1–2 days. Still a severe inflammation persists in the nasopharynx. Although such inflammation should naturally be understood by the redness of the mucosa, etc. its perfect diagnosis is seldom if ever possible because the light can hardly reach this part of the body and the nasopharyngeal mucosa is primarily red in color The presence of this inflammation cannot be observed sufficiently and exactly by simple optical methods. Therefore the method must depend for accuracy on the diagnostic method described by the author as follows.

The Method of Diagnosis of Nasopharyngitis

The diagnostic method for nasopharyngitis developed by the author is as follows as a diagnostic procedure the abrasion of the regional mucosa is exclusively applied without depending upon optical methods. In cases with severe inflammation the abrasion of nasopharyngeal mucosa especially of the dorsal surface of the soft palate by (nasal and pharyngeal) swabs is accompanied by severe pain followed frequently by postabrasive mucosal hemorrhages. The abrasion pain may often persist after abrasion and if intense even for several hours. In cases with severe hemorrhages the blood flows down through nasal cavities or pharynx and the hemorrhages often continue though only in small quantities, even for several hours. Such hemorrhages due to abrasion of the nasopharyngeal mucosa demon

strate the presence of erosion on the mucosal surface.

The pain during and after abrasion of the nasopharyngeal mucosa with local hemorrhages establishes proof of the presence of inflammations, especially of acute or subacute ones. This fact will be confirmed by clinical course of the ailment and by the transition of smears from mucosal abrasion specimens observed successively during the course. The previously mentioned abrasion pain or post abrasive hemorrhages, as stated already parallel the severity of inflammation found in the smears. When hemorrhages or pain during treatment is gradually reduced only by nasopharyngeal local treatment (daily application of 1% $ZnCl_2$) the cytological findings of the smears will be, in accordance with the treatment, gradually improved and finally in the smears from the nasopharyngeal mucosa will be lacking entirely in abrasion pain and hemorrhages, desquamated epithelial cells will be scarce, wandering cells will disappear completely and bacterial content will also be decreased markedly.

In regard to the nasopharynx, in short, inflammations are originally present, so its normal aspect does not appear till these inflammations are cured. Cases in which almost normal smears can be obtained unless treated from beginning are seldom, if ever to be found. According to our investigation moderate inflammation was found in 69.8 % of 202 school-children examined and marked nasopharyngitis was, as will be mentioned later found in about 80% of 4 000 out-patients.

The findings in cases with severe inflammation are given in the following in comparison with those in almost healed cases.

Findings	Nasopharyngitis marked	Nasopharyngitis slight
Epithelium	Desquamation & Deformation, marked	Normal Epithelial Cells
Wandering Cells	present	(−)
Bacterial Content	increased in number and kind	very low
Abrasion Pain	(++)	(±)~(−)
Postabrasive Hemorrhage	(++)~(+)	(−)

The local diagnosis of nasopharyngitis is, in consideration of these results, to be made as follows:

1. Abrasion pain in the nasopharyngeal mucosa caused by swabs.

2. Hemorrhages during abrasion of the nasopharyngeal mucosa caused by swabs (only in cases of marked inflammation with erosion)

3. Smears of nasopharyngeal abrasion specimens (smears prepared with abrasion swabs)
   - i. Desquamated epithelium: Papanicolaou Staining
   - ii. Wandering cells: Giemsa Staining
   - iii. Bacteria: Culture, identification, oil immersion

Furthermore, the posterior rhinoscopic and nasopharyngoscopic findings are also to be referred to. Nasopharyngitis exists always or almost always regardless of the presence or absence of inflammations of adjacent organs, so that even the absence of inflammations of adjacent organs, e.g. of tonsillitis or pharyngitis, does not afford conclusive evidence against the presence of nasopharyngitis.

8 Observations of the Course of Nasopharyngitis (Especially with Alterasion of Abrasion Pain)

In the preceding chapter it was stated that the diagnosis of nasopharyngitis cannot be made definitely by any of the hitherto known oto-rhinolaryngological methods, but only by cytological examination of smears obtained from nasopharyngeal mucosa and by observation of abrasion reactions such as pain or hemorrhages and that the abrasion of nasopharyngeal wall (dorsal surface of the soft palate) can be done without any difficulty and specimens can be obtained without causing any damage to the local tissue, as long as the inflammation is not severe (in cases of severe inflammation with mucosal erosion—probably due to formation of minute granulation tissue— the abrasion with swabs easily causes mucosal damages, but this management itself constitutes local treatment) This method is, therefore to be applied even everyday and only swabs for local treatment of nasopharyngitis dipped in 1 ZnCl$_2$ (or any other corrosive agent) and applied (always carefully and sufficiently) to the nasopharyngeal mucosa can obtain abrasion specimens for smears which are to be observed successively (even daily without trouble) so that the nasopharyngitis can be observed in this entire course.

Our object of observation in cases of nasopharyngitis was to examine three smears obtained as above at the time of daily treatment and stained each for desquamated epithelial cells wandering cells and bacteria The treatment consists as stated already of the application of 1 ZnCl$_2$ (eventually with small quantities of xylocain added) with swabs to nasopharyngeal mucosa so we have thoroughly studied for the first time the effects of drugs added to each of the specimens. No essential differences in the effect of abrasion by swabs with and without drugs were noted at least as far as determined on smears. In collecting bacteria for culture, for instance, sterilized swabs should be used and care must be taken not to bring the swabs at the time of collection into contact with the mucosa of oral cavity mesopharynx or nasal cavities. Of course nasopharyngitis, judging from the findings of such smears however is profoundly influenced by the presence of pain hemorrhages, etc. at the time of abrasion The fact that the pain of abrasion of the nasopharyngeal mucosa parallels the intensity of the inflammation, applies not only to the nasal mucosa but also to the meso- and hypopharynx, the inner surface of the esophagus, etc.

Great importance has been attached as you know to calor dolor tumor and rubor as classical criteria for inflammation, of which the three criteria other than rubor are mostly disregarded as far as mucosal inflammation is concerned. Of course this definition is not necessarily to be applied directly to mucosal inflammation. From the correlation of the findings of smears and abrasion pain with, however it should be considered that the dolor caused by abrasion may play the most significant role at least in the development of nasopharyngeal inflammation.

The dolor which has been considered to be of little significance in mucosal inflammation, however should play a more significant role as far as the nasopharynx (where the redness cannot be as satisfactorily observed as the other parts of the mucosal tissue) is concerned and its importance must be taken into consideration in observing the clinical course

Abrasion Pain and Nasopharyngitis

As stated above clinical observation of abrasion pain (as well as hemorrhages at the time of abrasion) in parallel to smears or if necessary the observation of nasopharyngitis in its entire course in terms of abrasion pain rather than smears, makes it possible to distinguish inflammatory conditions. The results are as follows

1 Acute Nasopharyngitis

In this case the abrasion pain is most marked and with frequent hemorrhages, and not rarely as stated already local abnormal feeling appears (In most cases the so-called feeling of a cold is observed) This is due to a stimulation of the autonomic nerves by acute nasopharyngitis, so the treatment of the nasopharynx readily cures colds and makes possible the prevention of colds as well. The soft palate will often be slightly paralyzed and in consequence the voice becomes slightly hoarse from a cold. This is an open nasal voice characteristic in m, n, ŋ etc., unlike the closed nasal voice of acute rhinitis due to a cold. Such acute nasopharyngitis should properly however be referred to as an acute exacerbation of nasopharyngitis When nasopharyngitis manifests itself, the symptoms of a cold, as mentioned earlier such as fever etc. may become evident. Daily observation of the course of nasopharyngitis with nasopharyngeal abrasion specimens reveals, however that an acute exacerbation can also be encountered in the first even without manifestation of cold and differs widely in grade too

After an established acute exacerbation, however the abrasion pain of nasopharyngeal mucosa more or less increases. Nasopharyngitis exists latently in a large number of people troubled with recurrent acute exacerbation however the reason for this fact raises difficult problems. The author' own opinion has already been given.

2 Subacute Nasopharyngitis

This is the most common and, therefore, the most frequent type of nasopharyngitis. Strictly speaking, we cannot, however draw a fine between acute and subacute nasopharyngitis. Subacute nasopharyngitis may therefore, represent only average nasopharyngitis. By subacute nasopharyngitis we mean the type of nasopharyngitis other than the previously mentioned acute nasopharyngitis or the chronic nasopharyngitis. Its characteristics are as follow

i. Local abrasion pain occurs during and after abrasion of nasopharynx.
ii. Desquamation of the epithelium is marked in the smears.
iii. Bacteriological examination reveals the so-called chronic phlogistic bacteria, such as pathogenic staphylococci, gram-negative bacilli, etc.
iv. No local symptoms are complained of except at the time of abrasion.
v. Erosion is common in acute cases however it also occurs in subacute and especially in infantile cases.
vi. The disease responds often and readily to local treatment.

3 Chronic Nasopharyngitis

By "chronic nasopharyngitis" we mean a process that occurs, but not very frequently Briefly its symptoms are as follows

i. (Purulent) rhinorrhea.
ii. Abundant neutrophil leucocytes in the smears with marked desquamation and degeneration of epithelial cells.
iii. Abrasion pain and bleeding not very marked.
iv. Relatively long course despite treatment, etc.

The abrasion pain is more or less marked, except in chronic cases, and the more marked the pain is, the more evident the symptoms may become. In acute and subacute cases, however the inflammation can generally be improved rapidly by local treatment, but in some cases the local treatment is not always effective and the abrasion pain remains for a long period of time. In such cases only a slight effect of the nasopharyngeal therapy on general diseases is to be expected.

The local therapeutic effect on abrasion pain and postabrasive hemorrhages was observed by SAITO (1963) in 30 cases of nasopharyngitis in our clinic. 1 $ZnCl_2$ solution was applied daily to the nasopharyngeal mucosa (especially of the dorsal surface of the soft palate) and then

Table 17 Days until disappearance of abrasion pain and abrasion hemorrhage during successive treatment of nasopharyngitis.

days		2 5	10	15	20	30	total

pain and hemorrhages after application were observed in detail The results were as given in Table 17 namely despite probable long standing inflammation before therapy the abrasion pain and postabrasive hemorrhages disappeared at the latest within 1 month after therapy and in the great majority of cases, within 15 days. The desquamation of the epithelial cells was improved, as shown in Table 18 running parallel to clinical manifestations such as abrasion pain etc.

In 1/5 of the cases little improvement was observed for instance in desquamation of epithelial cells, despite treatment. Such cases probably pertain to the so-called chronic nasopharyngitis, and the cases with abrasion pain or postabrasive hemorrhages which are favorably influenced by treatment are defined as subacute (as well as acute) nasopharyngitis.

9 Epidemiology of Nasopharyngitis

As mentioned in the first chapter nasopharyngitis exists latently in large number of people, and pathological examination revealed the presence of inflammation in all subjects aged from 12 hours after birth to 80 years. By the bacteriological examination of nasopharynx of infants, as shown in Table 5 staphylococcus epiderm. is found in 4 out of 14 cases even on the first day after birth, and thereafter the various kinds of bacteria increased gradually. Only few cases remained sterile beyond the fourth day. Although the contamination with bacteria does not necessarily cause inflammation immediately in the majority of cases, such the one of nasopharyngeal inflammation 12 hours after birth, it is supposed that the infection can be caused very early by atmospheric dust particles and the bacteria attached thereto.

In Table 19 the results of nasopharyngeal examination are given, which were performed on 202 primary school children in the city of Tokyo, especially in districts with a contaminated atmosphere. Their inflammatory states were studied by smears. This examination revealed that nasopharyngitis was marked in 83 cases (42.1%) and moderate in 56 cases (27.7%), so it was evident in a total of 69.8% but without subjective symptoms in the majority of cases. In other words nasopharyngitis was present in about 70% of the school children.

The examination of 4,616 patients visiting our ENT-Clinic revealed, as shown in Table 20,

Table 19 Frequency of nasopharyngitis in school children (1964, 13)

60–	301	195 (65.0%)	36 (11.9%)

that subacute or chronic nasopharyngitis was present in 67.4% and these cases are, as an interesting fact, quite similar to those of the school children. A so-called cold was found in 15.9% of the cases.

The incidence of nasopharyngitis is, therefore, altogether more than 80%. From the fact that an acute exacerbation of nasopharyngitis occurs in case of a cold and in consideration of the morbidity of a cold in the majority of cases, it is no wonder that such a high incidence of latent inflammation can be found.

In Table 21 the same cases were shown in respect to each age group. From this table it can be seen that the incidence-ratio between subacute or chronic and acute inflammation differs widely with different age groups, i.e. less than and more than 9 years of age. Namely in cases of less than 9 years of age the acute inflammation is common, whereas the subacute one is rather rare. From the clinical point of view severe inflammation such as erosion in its acute exacerbation should actually be found in

10 Significance of Nasopharyngitis for the Whole Body

Examination of nasopharyngitis by our methods reveals that remarkable inflammatory findings persist also in the nasopharyngeal mucosa already free from local symptoms after a cold, and further in cases without an existing cold nasopharyngeal examination also shows intensive inflammation frequently. The majority of the hosts (carriers of inflammation) are not conscious of the existing inflammation of the nasopharynx at all. Therefore, in most cases the nasopharyngitis proceeds without being noticed.

This fact is one of the most important characteristics of nasopharyngitis. In the presence of certain disease, especially inflammation, there should usually be some abnormalities in the region, of which the patient complains and sees physician for.

The local symptoms suggest the beginning of the disease, for instance, otorrhea, otalgia, defective hearing etc. in otitis media and anal hemorrhages or pain in hemorrhoids, therefore, the complete disappearance of such symptoms should be identical with recovery. The early detection of the diseases, for instance of malignant tumors before symptomatic manifestation has been attempted due to the gradual progress in medical science, which facilitated great progress in the field of medicine.

At present, however, the chief complaints of external manifestations are only criteria of the disease at least as far as inflammation is concerned. This means probably that little progress has been made in the conventional view which regards *inflammation, unlike malignant* tumors, as a less important disease necessitating *little* or no early detection. *It might reasonably* be expected that progress in the field of today medicine be made along this line of study.

Nasopharyngitis is a disease left behind as a subject of medical investigation up to this time. If the nasopharynx has *only a local inflammation*, there are no complaints from the beginning and therefore *no complaints are made at* the time of recovery so that medical science seems to have nothing to do at all with such local inflammation. The nasopharyngitis has, however very *significant effects on the whole* body and if *its treatment throw much new light on a hitherto unknown field of treatment*, this also raises significant problems for us.

This is the main reason that we have been made efforts to establish a practical method of diagnosis.

Inflammations of the nasopharynx exist independently and are for the most part not complicated by inflammation of the adjacent organs such as pharyngitis, rhinitis, etc. In these cases, therefore no inflammatory findings are to be obtained at all simply by observation of the mesopharynx or nasal cavities. Although *this fact does not concern directly observation of* the nasopharynx, however if we regard the nasopharynx as a part of the pharynx or nasal cavities, the absence of inflammatory changes in the immediately adjacent organs or in seemingly the same organ would normally rule out the existence of nasopharyngeal inflammations. This fact is, though not so important in leading to the diagnosis of nasopharyngitis itself, of much diagnostic significance in cases of nasopharyngitis.

Nasopharyngitis cannot always be sufficiently diagnosed by the torhinopharyngolaryngological diagnostic methods prevalently applied i.e. by only optical methods such as posterior *rhinoscopy* nasopharyngoscopy etc. Nasopharyngitis, unlike tumor or adenoids, does not cause morphological changes, its chief manifestation consists for the *most part merely of* mucosal redness, and findings such as posterior *rhinorrhea*, etc. are, *if they exist at all of relatively* rare occurrence. It will easily be understood that correct determination even of a

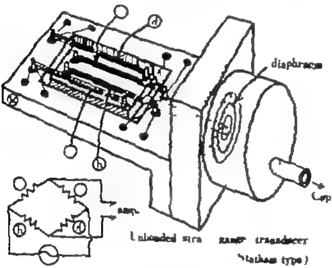
infantile cases much more frequently than in adult cases.

From the above it is clear that the nasopharynx is the most important of the common foci of inflammation.

11 Stimulation of the Nasopharynx and the Autonomic Nervous System

1) Stimulation of the Nasopharynx and Vasomotor Reflex

W have found the fact that the small blood essels of the fingertip are easily constricted by stimulation of the nasopharyngeal wall (HARADA, 1968) The fingertip volume—pulse wave can be obtained as follows. The changes of the air content in a finger cup put tightly on the fingertip is converted into electric current by a straingauge and amplified to obtain an oscillogram (Figs. 20, 21) Such plethysmographic observations of pulse waves in the fingertip reveal a marked contraction in them during abrasion of the nasopharyngeal walls by nasal or pharyngeal swabs. In normal cases, how ever the constriction continues only for 10–30 seconds and returns to its initial value. In Fig 22, a momentary contraction of the pulse wave is



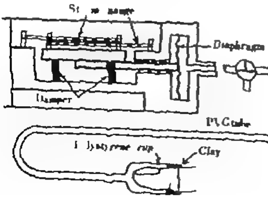


Fig. 20. Pneumatic strain gauge plethysmography

little increase of mucosal redness by optical methods is practically impossible, since the normal mucosa itself is originally reddish in color observation of the redness of the naso-pharynx, which can be observed only with difficulty and cannot be sufficiently illuminated is still more difficult. Thus the optical method does not suffice for the perfect understanding of nasopharyngitis. Only direct abrasion can make the diagnosis possible. This is another reason why this disease has been left behind as the subject of medical studies.

11 Stimulation of the Nasopharynx and the Autonomic Nervous System

1) Stimulation of the Nasopharynx and Vasomotor Reflex

We have found the fact that the small blood vessels of the fingertip are easily constricted by stimulation of the nasopharyngeal wall (HARADA, 1968) The fingertip volumo—pulse wave can be obtained as follows The changes of the air content in a finger cup put tightly on the fingertip is converted into electric current by a straingauge and amplified to obtain an oscillogram (Figs. 20, 21) Such plethysmographic observations of pulse waves in the fingertip reveal a marked contraction in them during abrasion of the nasopharyngeal walls by nasal or pharyngeal swabs. In normal cases, however the constriction continues only for 10–30 seconds and returns to its initial value. In Fig. 22, a momentary contraction of the pulse wave is

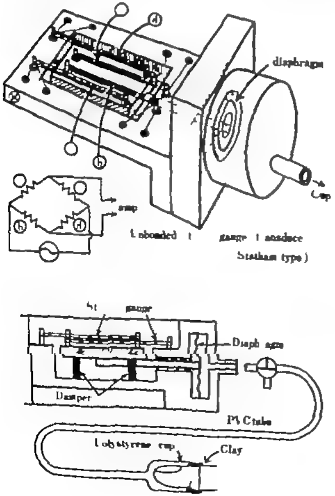

Fig. 20. Pneumatic strain gauge plethysmography

shown. Twenty healthy adults without abnormalities in the autonomic nervous system were examined by this method, and the results obtained are given in Table 22

The constriction time of the blood vessels of the fingertip under stimulation of the nasopharynx of 20 healthy subjects was less than 10, up to 15 20 and 30 seconds in 4 10 5 cases and 1 case respectively The normal constriction of the blood vessels of normal subjects under

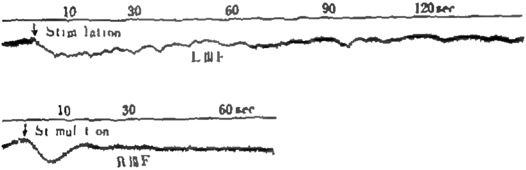

Fig 23. abov Case of prolonged constriction time. down Normal case.

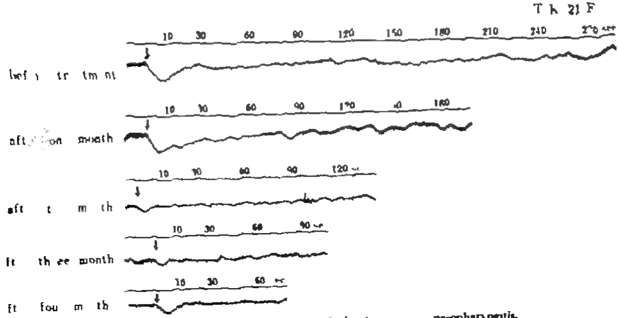

Fig 24. Change of duration of construction during tre nasopharyngitis.

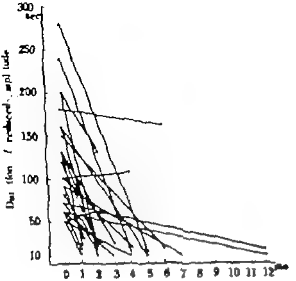

Fig. 25. Changes in finger vasomotor reflex in course of treatment.

nasopharyngeal stimulation was found to last about 15 seconds. In this way the reactions of the pulse waves of the fingertip with nasopharyngeal stimulation in each case were classified, so the constriction time was found to be markedly drawn out some cases beyond the normal limit mentioned above. In one case the constriction time is especially long as compared with that of about 15 seconds in normal cases in Fig. 23. Thus the constriction in certain cases cannot be restored for 60, 120 seconds, and even for 30 minutes or several hours. In such cases the examination reveals surely the presence of a severe nasopharyngitis. Further study has revealed that this elongation of the constriction time is closely related to the so-called autonomic nervous symptoms. Such an elongation of the constriction time can also be improved gradually by local treatment of nasopharyngitis and be restored finally to its normal value of about 15 seconds. An example of such cases is given Fig. 24: the constriction time of 270 seconds at the first but was reduced to 180, 120 and 90 seconds 1, 2 and 3 months after the beginning of treatment for nasopharynx respectively and returned to its normal level after treatment for 4 months.

In such cases with abnormal lengthening of digital pulse wave constriction time by nasopharyngeal stimulation, the pulse wave constriction can be normalized by local treatment of nasopharyngitis very frequently and, as shown in Fig. 25, indeed in almost all cases. In Fig. 25 the duration of therapy before restoration of pulse wave and its constriction time are given on the abscissa and the ordinate, respectively. The comparison of the constriction time before and after nasopharyngeal treatment reveals, as shown in Fig. 26, that it has been markedly improved in the latter. These data, though they are the same as in the

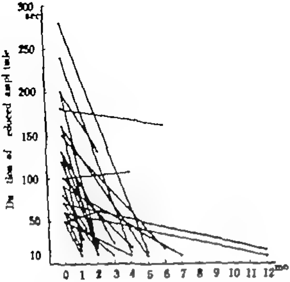

Fig. 23. Changes in finger vasomotor reflex in course of treatment.

nasopharyngeal stimulation was found to last about 15 seconds. In this way the reactions of the pulse waves of the fingertip with nasopharyngeal stimulation in each case were classified, so the constriction time was found to be markedly drawn out in some cases beyond the normal limit mentioned above. In one case the constriction time is especially long as compared with that of about 15 seconds in normal cases in Fig. 23. Thus the constriction in certain cases cannot be restored for 60–120 seconds, and even for 30 minutes or several hours. In such cases the examination reveals surely the presence of a severe nasopharyngitis. Further study has revealed that this elongation of the constriction time is closely related to the so-called autonomic nervous symptoms. Such an elongation of the constriction time can also be improved gradually by local treatment of nasopharyngitis and be restored finally to its normal value of about 15 seconds. An example of such cases is given in Fig. 24: the constriction time of 270 seconds at the first visit was reduced to 180, 120 and 90 seconds 1, 2 and 3 months after the beginning of treatment for nasopharyngitis respectively and returned to its normal level after treatment for 4 months.

In such cases with abnormal lengthening of digital pulse wave constriction time by nasopharyngeal stimulation, the pulse wave constriction can be normalized by local treatment of nasopharyngitis very frequently and, as shown in Fig. 23 indeed in almost all cases. In Fig. 23 the duration of therapy before restoration of pulse wave and its constriction time are given on the abscissa and the ordinate, respectively. The comparison of the constriction time before and after nasopharyngeal treatment reveals, as shown in Fig. 26, that it has been markedly improved in the latter. These data, though they are the same as in the

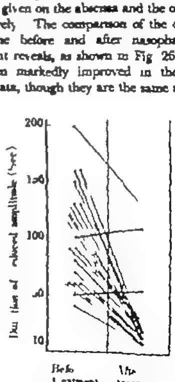

Fig. 26. Restoration of pulse wave after nasopharyngeal local treatment; comparison before and after treatment.

Fig 25 are enough to indicate therapeutic effect.

The fact that the nasopharyngeal stimulation causes a marked constriction of small digital vessels and eventually an abnormal lengthening of the constriction time is of considerable importance.

The constriction of small digital blood vessels through the vasomotor nerve while the autonomic nerve responds to a stimulus. The vascular constriction is probably the result of an adrenergic effect and though the role of the sympathicus and the parasympathicus in the constrictions of blood vessels is not to be discussed here, it is at least certain that nasopharyngeal stimulation will produce considerable effects upon the autonomic nervous system. Through the plethysmography of the digital pulse wave therefore an objective method for determination of the effects of nasopharyngeal stimuli upon the autonomic nervous system has been developed. In cases of normal adults the autonomic nervous system responds to nasopharyngeal stimuli (through the scale of the digital pulse wave) commonly for about 15 seconds but eventually even 30 min or several hours as mentioned before even with stimuli of almost the same degree. Such cases with reaction of long duration are, moreover associated with severe nasopharyngitis without exception

The irritability of the autonomic nerve, being projected into the pulse wave constriction time as objective data makes possible the objective observation of the abnormality of the autonomic nerve and thus indicates certain progress in the field This fact has been realized through the disease nasopharyngitis Another fact of interest is that the normal state of the autonomic nerve can gradually be restored by the treatment of nasopharyngitis The therapeutic effect projected into the vascular motility in cases of nasopharyngitis, though it may not always be under special circumstances can express objectively the functional disorders of the vasomotor nerve and the autonomic nerve and control it consequently in a a sense In this case we are concerned naturally only with the vasomotor nerve however this effect considered together with that upon the blood pressure, as will be mentioned later is certainly a subject of deep interest.

2) Stimulation of the Nasopharynx and the Mecholyl Test

The *mecholyl test* originated by GELLHORN (1956) is one of the test methods for autonomic nervous function. This method consists in recognizing the functional state of the autonomic nervous system by the patterns of the blood pressure curve, while the systolic blood pressure is successively registered after the injection of a choline derivative, acetyl-β-methylcholine (Mecholyl) ORINAKA (1959 1960) classified these patterns according to the changes of the blood pressure once decreased after the *mecholyl* injection in any case into 3 types

1 S-type (Sympathetic hyperreactor) the blood pressure which is once decreased begins to increase again becomes 10 mmHg higher than before injection and thereafter returns gradually to its initial value.

2 N type (Normoreactor) the blood pressure, which is once decreased starts to increase, without becoming more than 10 mmHg higher than that before injection and returns to its initial value about 10 minutes after injection.

3 P type (Sympathetic hyporeactor) the blood pressure which is once decreased does not return to its initial value even after 10 minutes and remains decreased.

The S-type and the P type are regarded as abnormal types of autonomic nervous functions. In Fig 27 these processes are shown

It is a well known fact that this mecholyl test is a method for examination of vegetative dystonia Generally vegetative dystonia is mostly of a central nature so its examination methods are mostly psychological tests mainly developed and applied by SIEBECK, HARRST WENGER ABE et al to determine the psychological effects. There have been applied formerly as direct test methods for autonomic nerve function various tests with drugs such as adrenaline, pilocarpine atropine etc.

These tests with drugs as autonomic nerve toxins are not always applicable and can be dangerous when applied in cases with hypersensitivity of the autonomic nerve Are there not, therefore any test methods for functional

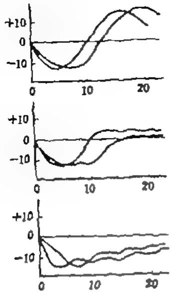

Fig. 27 Three types of Response of Mecholyl Test.

states of the autonomic nervous system without using drugs?

While we have taken notice of the relationship between the digital pulse wave constriction and nasopharyngitis and further nasopharyngeal stimulation and the autonomic nerve, we have felt interest in the response of blood pressure to nasopharyngeal stimulation instead of the mecholyl injection. On the subjects of each N- S- and P-type according to the above mentioned mecholyl test, the effect of nasopharyngeal stimuli upon blood pressure was observed. The observation of the successive changes of blood pressure was done in the same way as in the mecholyl test. As a result, in each case the blood pressure once increased directly after nasopharyngeal stimulation without exception, and thereafter changed in the closely similar way to that after its initial decrease in the mecholyl test. In Fig. 28 the changes of blood pressure caused by nasopharyngeal stimuli are given in each N- S- and P type of actual cases. The changes of blood pressure caused by nasopharyngeal stimuli are summarized as follows

1. Marked increase immediately after nasopharyngeal stimulation.

2. Three different modes of changes thereafter i.e.

3. The blood pressure once increased returns to its initial level before stimulation within almost 2 1/2 min. and alters little thereafter *(this corresponds to the N-type in the mecholyl test)*

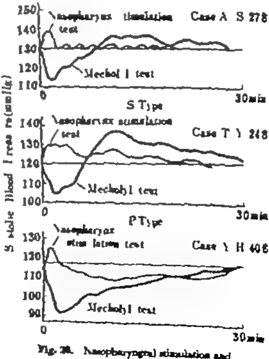

Fig. 28. Nasopharyngeal stimulation and Mecholyl test.

4 The blood pressure increased after the stimuli does not return to its initial value even after 3 min. or more, and increases further for several or scores of minutes (this corresponds to the S-type in the mecholyl test)

5 The blood pressure once increased after the stimuli begins to decrease immediately even beyond the initial level before stimulation and remains at its level for several or scores of minutes (this corresponds to the P type in the mecholyl test)

From these results it can be seen that the effects of nasopharyngeal stimuli resemble closely to those of mecholyl injection. The determination of changes of the blood pressure caused by nasopharyngeal stimulation is useful as a test method compatible with and more convenient than the mecholyl test

3) Vegetative Dystonia and Nasopharyngitis

In order to compare the nasopharynx stimulation blood pressure curve (hereafter referred to as NSBP) mentioned above and the degree of nasopharyngitis, 30 cases of erosive nasopharyngitis of especially marked degree showing post abrasive pain and hemorrhages were selected for determination of NSBP The results obtained are given in Table 23 In serious cases, as seen in Table 23 S- and P type are most frequently seen and the both types together show the high percentage of 80

On the contrary of 10 (seemingly almost normal) cases of slight nasopharyngitis 2 were of S-type and 1 was of P type and 7 cases, i e. the high percentage of 70 were of N type By this fact it has been shown that the degree of nasopharyngitis is, in a sense related with the autonomic nervous disturbances. The types of the autonomic nervous system have hitherto been understood as being classified constitutionally however it is important that it has been elucidated that they are related with the nasopharyngitis, a superficial inflammation occurring a posteriori

If it is possible for us to normalize the abnormal blood pressure patterns by local treatment of nasopharyngitis, it should be said that it has become possible to control the abnormal autonomic nervous pattern. Regarding such possibilities we have spoken in the previous chapter about the digital pulse wave and further possibilities with regard to NSBP will be mentioned in the next chapter

4) Treatment of Nasopharyngitis and Blood Pressure Curve after Nasopharynx Stimulation

The above blood pressure curve obtained after nasopharyngeal stimulation can be as after the mecholyl injection regarded as a manifestation of the blood pressure pattern of the autonomic nerve and it is also possible in this case as in the previous case of the digital pulse wave to convert an abnormal pattern to a normal one by prolonged treatment of the nasopharynx. *Fig 29 a.* shows the method of stimulating or treatment of nasopharynx. Fig 29 shows the case of a 59 year-old male treated in this way His chief complaint at the first examination was *headache* (headache and nasopharyngitis are closely related with each other as will be mentioned in detail in the pertinent paragraph)

At the first visit in this case local pain and postabrasive hemorrhages were marked at abrasion of the nasopharynx The local pain and the chief complaint disappeared after treatment of 1 and 2 months duration respectively and the NSBP observed together changed as follows The NSBP was S-type at the time of abrasion P type after one month and N type after 2 months. In this case the result of the mecholyl test was S-type in the initial stage with NSBP of S-type The result of the mecholyl test two months after the treatment for nasopharynx was found to be changed into N type In this case the digital pulse wave was not observed. In the other cases, in which the digital pulse wave contriction was prolonged in those with NSBP of P and S-type and when the NSBP become N type after treatment the pulse wave returned also to its normal value In this case therefore the S-type in the beginning changed into the N type after 2 months of the treatment of the simultaneously but latently

existing nasopharyngitis.

The constitution has been regarded as a conclusive factor in determining the type of the autonomic nerve, which can be altered temporarily but not permanently by administration of drugs. however. It was found that such an *abnormal type can be changed into the normal type by local treatment of a hidden inflammation, nasopharyngitis*, as shown in Tables 24 and 25. The local treatment for nasopharynx was done daily in 30 cases of severe nasopharyngitis, as is shown in the tables, and 24 and 6 cases were of abnormal and normal type before treatment, respectively. after treatment the abnormal type was found only in one case and all the other 29 cases returned to the normal type.

In these healed cases the type remained normal for a fairly long period after a prolonged treatment, and this aspect awaits clarification

through detailed studies in the future. If recurrent acute exacerbation of nasopharyngitis occasionally due to a cold occurs during the course of improvement the blood pressure curve often becomes abnormal but it returns to the normal curve easily after another treatment of the nasopharynx. This aspect applies also to the digital pulse wave mentioned above

The mecholyl test has been applied for detection of the autonomic nervous disorders, and the results have been useful as a subsidiary method or a conclusive factor for psychological examination of various autonomic nervous functions however the mecholyl itself is often thought to be dangerous since it affects at times deeply the autonomic nervous mechanism. On the contrary nasopharyngeal stimulation is not only not dangerous, but also as effective as mecholyl so it could be available in the future for functional examination of the autonomic nerve

5) Control of the Autonomic Nerve

In the chapters on the digital pulse wave and the nasopharynx stimulation blood pressure curve it was stated that the blood vessel motility and the blood pressure are related very closely with the nasopharyngitis and therefore the nasopharyngeal stimulation makes possible the examining of the functional state normal and abnormal of the autonomic nerve Furthermore the abnormal state of the autonomic nerve revealed by these examinations was restored gradually by treatment of the nasopharynx, and the restored state remained semipermanently

It is a very interesting fact that an abnormal state of the autonomic nerve can be returned to its initial normal state by treatment of nasopharyngitis. It has been previously impossible for us to restore the autonomic nerve in its abnormal state to the normal state The autonomic nerve in the abnormal state could be restored e g by administration of certain drugs, not permanently but only temporarily The abnormality of the autonomic nerve has been therefore regarded not as a state but as a constitutional and permanent feature The autonomic nervous disturbances have been considered as a state not to be controlled by man. It is an interesting fact that the local treatment of nasopharyngitis made it possible to restore the autonomic nervous disturbances regarded as uncontrollable

The autonomic nervous disturbance manifests generally various symptoms. This abnormal state is, moreover situated between the soul and body so it will be considered as of psychogenic or of purely organic nature. For instance headache or palpitation will belong to the soul (in the present paper headache is not considered as a state influenced by the autonomic nerve) but the changes such as gastric ulcer etc. are probably organic changes pertaining to the body To study the possible relationship between the autonomic nerve and a certain disease the carriers of the disease have commonly been tested for a hypersensitive state of the autonomic nerve. Such a state of the autonomic nerve can be tested in two ways, namely by psychological examination and by a response test after injection of autonomic nerve toxins. The methods of SIEBECK (1939) HERBST WENGER (1947) etc. and in Japan, of IKEMI (1966) ABE (1960) etc are regarded as the former All of these methods consist in psychological examination requiring answers to various questions. On the contrary these are tests for toxicity of drugs, such as adrenaline, pilocarpin atropine noradrenaline mecholyl etc. and these for response to the direct physical stimuli such as ASCHNER s method CZERMAK HERING s method, cold pressor test test through change of position, etc. or dermography There are so many test methods used because the response to the stimuli is not always stable while various methods including the psychological one indicate that the autonomic nervous system is unconditionally and inevitably controlled by the central nervous system.

The cause for this unstability will be attributed to the fact that the autonomic nerve is not always in a stable state but is, especially in the so-called 'neurotic patients, in an exceedingly changeable state correspondingly regulated by the central nervous system, so it remains difficult to understand its pathological features by examination.

This problem is to be solved only by possible restoration of the autonomic nerve to a stable state In this sense the normalization of the above mentioned abnormal state of the auto-

nomic nerve by nasopharyngeal treatment has certainly enlarged our biological knowledge of the autonomic nerve. In the following we want to observe how the patients with various complaints, the so-called autonomic nervous symptoms stated in the above, can be improved by nasopharyngeal treatment.

As the so-called autonomic nervous symptoms, SUZUKI has indicated various signs, from which we have selected the following ten as main symptoms. Each of these symptoms is present frequently as a separate or compound complaint and can be improved by nasopharyngeal treatment with marked response. There will be given in detail in the following such symptoms, of which e.g. headache, dizziness, diarrhea, gastric ulcer etc. are representative. The 10 main symptoms are as follows:

i. Cutaneous symptoms: 1. cold feeling 2. hot feeling 3. abnormal secretion
ii. Cardiac symptoms: 4. palpitation 5. pulsus celer unstable pulse
iii. Vascular symptoms: 6. dizziness 7. migraine 8. variable blood pressure
iv. Gastrointestinal symptoms: 9. constipation 10. diarrhea

The patients with a so-called neurosis generally have many such complaints. Such autonomic nervous complaints have been regarded as complaints without any known cause and being probably of psychogenic origin, so that administration of psychostatic drugs or psychotherapy has been done without its being a definite treatment. The observation of the prolongation of the digital pulse wave constriction time caused by the previously mentioned nasopharyngeal stimulation, especially upon the patients with the above mentioned neurotic complaints, reveals positive prolongation of the digital pulse wave constriction time in most cases.

So far as the vasomotor nerve of the peripheral blood vessels is concerned, the hypersensitivity of autonomic nerve was often found in patients with neurotic symptoms. So we have observed many of these patients, as shown in Table 26 and attempted to compare the digital pulse wave constriction time under nasopharyngeal stimulation with the number of autonomic nervous symptoms indicated by SUZUKI as above (e.g.

Table 26 Relation between finger vasomotor reflex and autonomic nervous symptoms

Duration of reduced amplitude	Autonomic nervous symptoms: Number of positive symptoms									
	1	2	3	4	5	6	7	8	9	10
> 30 sec	7	7	3							
30–59	1	1		2						
60–119			2	7	4	1	1			
120–300			2	2	3	2	2	1		
300 <					1		1			

3 if a patient complains of cold feeling in the skin, dizziness and migraine).

The number of complaints and the period of prolongation (sec) of the pulse wave have been compared with each other. This comparison has revealed that there is a close correlation between the prolongation of the pulse wave constriction time caused by nasopharyngeal stimulation and the number of complaints of the patient. To this correlation much significance can be attached, so the autonomic nervous symptoms regarded hitherto as of psychogenic origin are in fact not always of psychogenic origin but also projected considerably into the (so to speak organic) pathological changes of the autonomic nerve itself. This has been realized only through stimulating the nasopharynx, and, in fact, has proved the possibility of replacing at least the psychogenic, completely intractable phenomena with the autonomic nerve as a more or less objective matter.

In the previous chapter it was indicated that the constriction of the digital pulse wave caused by nasopharyngeal stimulation and the abnormalities in the blood pressure curve after stimulation can be restored by local treatment of nasopharyngitis in the majority of cases. Is it not possible to apply this fact to the relationship between the prolongation of the pulse wave and the autonomic nervous symptoms (complaints)? The various kinds of autonomic nervous symptoms such as headache, dizziness and others are almost always accompanied by nasopharyngitis and most of these essentially autonomic nervous symptoms have been known to disappear during local therapy for nasopharyngitis as the nasopharyngitis improves. If prolongation of the pulse wave and autonomic nervous disturbance coexist in one and

through detailed studies in the future. If recurrent acute exacerbation of nasopharyngitis occasionally due to a cold occurs during the course of improvement the blood pressure curve often becomes abnormal but it returns to the normal curve easily after another treatment of the nasopharynx. This aspect applies also to the digital pulse wave mentioned above.

The mecholyl test has been applied for detection of the autonomic nervous disorders and the results have been useful as a subsidiary method or a conclusive factor for psychological examination of various autonomic nervous functions however the mecholyl itself is often thought to be dangerous, since it affects at times deeply the autonomic nervous mechanism. On the contrary nasopharyngeal stimulation is not only not dangerous, but also as effective as mecholyl so it could be available in the future for functional examination of the autonomic nerve

5) **Control of the Autonomic Nerve**

In the chapters on the digital pulse wave and the nasopharynx stimulation blood pressure curve it was stated that the blood vessel motility and the blood pressure are related very closely with the nasopharyngitis and therefore the nasopharyngeal stimulation makes possible the examining of the functional state normal and abnormal of the autonomic nerve Furthermore the abnormal state of the autonomic nerve revealed by these examinations was restored gradually by treatment of the nasopharynx, and the restored state remained semipermanently

It is a very interesting fact that an abnormal state of the autonomic nerve can be returned to its initial normal state by treatment of nasopharyngitis. It has been previously impossible for us to restore the autonomic nerve in its abnormal state to the normal state. The autonomic nerve in the abnormal state could be restored e g by administration of certain drugs not permanently but only temporarily The abnormality of the autonomic nerve has been therefore regarded not as a state but as a constitutional and permanent feature The autonomic nervous disturbances have been considered as a state not to be controlled by man. It is an interesting fact that the local treatment of nasopharyngitis made it possible to restore the autonomic nervous disturbances regarded as uncontrollable

The autonomic nervous disturbance manifests generally various symptoms. This abnormal state is, moreover situated between the soul and body so it will be considered as of psychogenic or of purely organic nature. For instance headache or palpitation will belong to the soul (in the present paper headache is not considered as a state influenced by the autonomic nerve) but the changes such as gastric ulcer etc. are probably organic changes pertaining to the body. To study the possible relationship between the autonomic nerve and a certain disease the carriers of the disease have commonly been tested for a hypersensitive state of the autonomic nerve Such a state of the autonomic nerve can be tested in two ways, namely by psychological examination and by a response test after injection of autonomic nerve toxins. The methods of SIEBECK (1939) HERBST WENGER (1947) etc. and in Japan of IKEMI (1966) ABE (1960) etc. are regarded as the former All of these methods consist in psychological examination requiring answers to various questions. On the contrary these are tests for toxicity of drugs, such as adrenaline pilocarpin atropine noradrenaline mecholyl, etc. and these for response to the direct physical stimuli, such as ASCHNER s method, CZERMAK HERING s method, cold pressor test test through change of position, etc. or dermography There are so many test methods used because the response to the stimuli is not always stable while various methods including the psychological one indicate that the autonomic nervous system is unconditionally and inevitably controlled by the central nervous system.

The cause for this unstability will be attributed to the fact that the autonomic nerve is not always in a stable state but is, especially in the so-called neurotic patients, in an exceedingly changeable state correspondingly regulated by th central nervous system so it remains difficult to understand its pathological features by examination

This problem is to be solved only by possible restoration of the autonomic nerve to a stable state In this sense the normalization of the above mentioned abnormal state of the auto-

nomic nerve by nasopharyngeal treatment has certainly enlarged our biological knowledge of the autonomic nerve. In the following we want to observe how the patients with various complaints, the so-called autonomic nervous symptoms stated in the above, can be improved by nasopharyngeal treatment.

As the so-called *autonomic nervous* symptoms, SIEBECK has indicated various signs, from which we have selected the following ten as main symptoms. Each of these symptoms is present frequently as a separate or compound complaint and can be improved by nasopharyngeal treatment with marked response. There will be given in detail in the following such symptoms, of which e.g. headache, dizziness, diarrhea, gastric ulcer etc. are representative. The 10 main symptoms are as follows

i. Cutaneous symptoms 1. cold feeling 2. hot feeling 3. abnormal secretion
ii. Cardiac symptoms 4. palpitation 5. pulsus celer unstable pulse
iii. Vascular symptoms 6. dizziness 7. migraine 8. variable blood pressure
iv. Gastrointestinal symptoms 9. constipation 10. diarrhea

The patients with a so-called *neurosis* generally have many such complaints. Such autonomic nervous complaints have been regarded as complaints without any known cause and being probably of psychogenic origin, so that administration of psychostatic drugs or psychotherapy has been done without its being a *definite* treatment. The observation of the prolongation of the digital pulse wave constriction time caused by the previously mentioned nasopharyngeal stimulation especially upon the patients with the above mentioned neurotic complaints, reveals positive prolongation of the digital pulse wave constriction time in most cases.

So far as the vasomotor nerve of the peripheral blood vessels is concerned, the hypersensitivity of autonomic nerve was often found in patients with neurotic symptoms. So we have observed many of these patients, as shown in Table 26 and attempted to compare the digital pulse wave constriction time under nasopharyngeal stimulation with the number of autonomic nervous symptoms indicated by SIEBECK *as above (e.g.*

Table 26 Relation between finger vasomotor reflex and autonomic nervous symptoms

120–300			2	2	3	2	2	1		
300 <					1		1			

3 if a patient complains of cold feeling in the skin, dizziness and migraine)

The number of complaints and the period of prolongation (sec) of the pulse wave have been compared with each other. This comparison has revealed that there is a close correlation between the prolongation of the pulse wave constriction time caused by nasopharyngeal stimulation and the number of complaints of the patient. To this correlation much significance can be attached, *so the autonomic nervous symptoms regarded hitherto as of psychogenic* origin are in fact not always of psychogenic origin but also projected considerably into the (so to speak organic) pathological changes of the autonomic nerve itself. This has been realized only through stimulating the nasopharynx, and, in fact, has proved the possibility *of replacing at least the psychogenic,* completely intractable phenomena with the autonomic nerve as a more or less objective matter.

In the previous chapter it was indicated that the constriction of the digital pulse wave caused by nasopharyngeal stimulation and the abnormalities in the blood pressure curve after stimulation can be restored by local treatment *of nasopharyngitis in the majority of cases. Is it not possible to apply this fact to the relation*ship between the prolongation of the pulse wave and the autonomic nervous symptoms (complaints)? The various kinds of autonomic nervous symptoms such as headache, dizziness and others are almost always accompanied by *nasopharyngitis* and most of these essentially *autonomic nervous* symptoms have been known to disappear *during local therapy* for nasopharyngitis as the nasopharyngitis improves. If prolongation of the pulse wave and autonomic nervous disturbance coexist in one and

the same person and both can be restored by the treatment of nasopharyngitis, objective studies on the autonomic nervous symptoms become possible.

From this viewpoint the patients with many complaints were subjected to observation of the prolongation of pulse wave caused by nasopharyngeal stimulation and at the same time the parallelism between the changes of pulse wave and the improvement in complaints was observed during nasopharyngeal treatment in these cases. Two typical cases will be referred to in the following

Case (Table 27 Fig 30)

T Y 59 y ♂

Chief complaint

1 Susceptibility to eczema
2 Palpitation
3 Unstable pulsus tardus or celer
4 Migraine on the left side
5 Dizziness
6. Tendency toward constipation

In this case, in short 6 autonomic nervous symptoms are complained of. Observation of the nasopharynx revealed marked inflammation and the abrasion by swabs caused severe pain and profuse postabrasive hemorrhage. In the smears numerous ciliated cells (compatible with desquamation of many epithelial cells) were found which were, however almost normal in their shape, and yet the goblet cells were increased and the appearance of polymorphonuclear leucocytes, lymphocytes, etc. was marked. The prolongation of the pulse wave caused by nasopharyngeal stimulation extended over a period of 160 sec. In the course of treatment of the nasopharynx in this case, as shown in Table 27 and Fig 30 every complaint was gradually improved. The conditions such as palpitation, unstable pulse wave etc. were remedied and the dizziness disappeared one month after the beginning of treatment. Tendency toward constipation disappeared and the patient having a bowel movement every day was in great good humor At this time the prolongation of pulse wave was restored to its normal value of 20 sec. however the patient caught a cold early in the second month and the palpitation reappeared. At this time the pulse wave was again prolonged up to

60 sec. and nasopharyngeal abrasion caused again abrasion pain and postabrasion hemorrhage, which had once completely disappeared. During further treatment of the nasopharynx these acute symptoms disappeared soon, and the nervous symptoms were also improved gradually and in the 3rd month the symptoms such as palpitation and migraine, disappeared completely leaving only the eczema.

The pulse wave returned to its normal level of 10 sec. In the 4th month the eczema also disappeared and the autonomic nervous symptoms disappeared completely. Since then the pulse wave has remained at 10 sec. and no autonomic nervous symptoms have been found.

The symptoms such as headache, dizziness, eczema, etc. often showing a marked improvement equally by the nasopharyngeal treatment, were found to be improved in parallel to the prolongation of the pulse wave constriction time. Practically through the nasopharyngeal treatment it can be understood that the improvement of such autonomic nervous symptoms covers a wider range. For instance if a feeling of impatience, called hysteric stigmata, or of general fatigue associated with the above mentioned complaints was treated by nasopharyngeal therapy these feelings can frequently be improved according as those symptoms disappear. In cases only with feeling of fatigue or impatience furthermore, the nasopharyngeal treatment can often produce certain effects. A case of a female patient with such complaints, treated as hysteria, will be given in the following.

tion before and after chlorpromazine i jection are given in each left and right half of the left column, respectively. The digital pulse wave was in all 8 cases, except 2 (15 sec. 20 sec.) within the normal limits, extraordinarily prolonged. The cases in which the pulse wave constriction extended over a long period of time without being restored during the period of observation, are indicated in the column by cont. In these cases, however administration of chlorpromazine caused almost no constriction and even the nasopharyngeal stimulation was unable to produce changes in the pulse wave. There were found in a few cases certain changes, which were always within the normal limits. In the right column the changes of blood pressure after the nasopharyngeal stimulation are set down the changes before and after the injection of chlorpromazine on the left and right side, respectively. Namely the changes of blood pressure following nasopharyngeal stimulation before the injection were of abnormal type S or P except in 2 cases of N type however after the injection of chlorpromazine the changes of blood pressure following nasopharyngeal stimulation were of N-type without exception. It appears to be fairly well established from this experiment, that the presence of nasopharyngitis is very closely related to the autonomic nervous system.

Note 1

The digital cup has capacity of 14cc, an inside diameter of 20mm and an outside diameter of 22mm and is made of polyvinyl chloride. The middle finger is introduced into the cup, and its proximal end is fixed with clay so that the introduced finger will be made completely airtight.

The cup and the transducer (strain gauge) are connected to each other by polyvinyl tube having an inside diameter of 3mm and thickness of about 1mm. The polyvinyl tube should be, though flexible free of elasticity.

Note 2

The downward shift of the pulse curv means decrease of blood flow and the decrease of pulse amplitude, decrease of pulse pressure. In short this indicates the reduction of diameter of the peripheral blood vessels.

before consultation.
Diagnosis of neurosis at the internal clinic.
Findings at the first examination.
Autonomic nervous symptoms 1 coldness in the extremities, 2 palpitation, 3 dizziness, 4 constipation 5 diarrhea
Pulse wave constriction time 240 sec.
Nasopharyngeal findings.
Severe pain and postabrasive hemorrhages at the time of nasopharyngeal abrasion with pharyngeal swabs. There could be found in the smears from the abrasion specimen numerous ciliated epithelial cells with obscure ciliary structure, indistinct cuticular border and markedly swollen cytoplasma and a moderate number of wandering cells such as leucocytes, lymphocytes, etc.
Disappearance of abrasion pain and postabrasive hemorrhages of the nasopharyngeal wall within 6 weeks after the beginning of treatment. At that time excess general fatigue was found immediately after the beginning of treatment so that even standing was not endurable, but this was improved rapidly by further treatment. Movement was subjectively improved in the first week and in the second week the patient was further improved and even became highly energetic. Disappearance of palpitation and dizziness in the sixth week of treatment. Simultaneous decrease of the pulse wave constriction time to 110 sec. Furthermore in the third month of the treatment, complete disappearance of inflammatory features in the smears from the nasopharynx, and of all autonomic nervous symptoms except constipation, and restoration of the pulse wave constriction to a normal value of 15 sec.

In the above cases severe fatigue was improved of the cases with disturbances such as irritability however there are often also cases restored by the treatment of nasopharyngitis. In this connection it is interesting to note that a certain case of orthostatic regulatory disturbance was improved by treatment for nasopharynx, while the child in this case became lively and even the abnormalities of the patient s character such as late rising dislike of school fickleness etc were improved A matter of further interest is the masked depression. This means a depression occurring in association with rheumatism or hypertension and is not a true psychosis however this disease as well as the associated rheumatism or hypertension is possibly related to nasopharyngitis. From this possibility it may further be expected that nasopharyngitis without rheumatism or hypertension leads only to depression Under the conditions immediately after the treatment of nasopharyngitis the constriction of the digital blood vessels occurs, as mentioned already and in certain cases, the intracerebral blood vessels are also supposed to be particularly susceptible to this treatment. This possibility is suggested also by the constriction of the basilar blood vessels, while most patients complain of markedly decreased thinking power and drowsiness immediately after treatment Afterward however the patients become especially clear headed for a considerably long period On the basis of the possibility of such alterations in the small blood vessels of the brain we have also carried out a study of the constriction of the larger blood vessels of the brain on which it will be detailed later As a problem, what sort of relation is borne by the constriction of the digital pulse wave caused by nasopharyngeal stimulation to the variation of blood pressure (NSBP) immediately after stimulation? A close relationship between them may exist and its mechanism requires further study

Chlorpromazine Injection

The response of the autonomic nerve to nasopharyngeal stimulation and the effect of the treatment of nasopharyngitis on the autonomic nervous disturbance are referred to just above and what kind of variety will be given to abnormal states of the autonomic nerve detected through nasopharyngeal stimualtion by drugs? In this connection there have been observed the reactions caused by adrenaline noradrenaline, acetylcholin, chlorpromazine etc of which those caused by chlorpromazine were most interesting On 10 patients with autonomic nervous disturbances treatment with *i.m.* injection of 0 5mg/kg chlorpromazine and nasopharyngeal stimulations was performed before and after which the variation of the blood pressure and the digital pulse wave were studied On these patients preliminary studies on neurovegetative conditions (NSBP and pulse wave) before administration of drugs had been performed by stimulating the nasopharynx.

In the left and right column of Table 29 the digital pulse wave and the variation of blood pressure are set down. Changes of the digital pulse wave caused by nasopharyngeal stimula

ELT thus determined. As remarkable changes of ELT were observed when the nasopharynx was irritated ELT in Fig 32 was determined without irritating the nasopharynx before taking blood. However diagnosis of the nasopharynx can be done correctly only by abrasion of the nasopharyngeal mucosa. Therefore the nasopharyngeal mucosa was abrased in all patients after blood letting and it was decided whether they had nasopharyngitis by

1. abrasion pain
2. postabrasive hemorrhage, and
3. examination of the smears.

Those in whom the absence of inflammation could be determined according to the above standards were taken as controls and compared with those with nasopharyngitis. As shown in Fig. 32, ELT of controls was from 150 to 200 minutes, while in the group with nasopharyngitis, ELT varied extremely ranging from 50 to 500 minutes.

To study what this result suggested, patients with nasopharyngitis were divided into 3 groups, namely acute, subacute and chronic, and ELT of these 3 groups was investigated. (Acute nasopharyngitis was the stage of dry feeling of dorsal surface of the soft palate and slight rhinolalia aperta (open nasal voice). When touched with cotton applicator marked abrasion pain and bleeding were caused in the nasopharynx, and in the examination of the smears severe inflammation, namely significant transformation of the epithelial cells, and the appearance of wandering cells and various bacteria were observed. The most characteristic symptoms among these were abnormal feeling of nasopharynx and open nasal voice accompanied with so-called cold symptoms. Subacute nasopharyngitis is stage of the disease where local symptoms of acute nasopharyngitis disappear. Even after local symptoms disappear an inflammatory condition often remains continuously without any subjective symptoms. As mentioned before, this kind of inflammation is present in many persons. A chief complaint of chronic nasopharyngitis was postnasal discharge, which was caused by pus excreted from the nasopharyngeal mucosa itself and not by sinusitis. Those with chronic nasopharyngitis did not feel much abrasion pain in the nasopharynx. In spite of that significant changes were observed in the examination of the smears, such as transformation and desquamation of the epithelial cells and wandering of neutrophiles and lymphocytes. This is an outline of classification of the 3 types of nasopharyngitis.)

Fig 33 shows ELT corresponding to the 3 types of nasopharyngitis classified according to the above standards. From these results it is seen that ELTs of acute nasopharyngitis were shorter than 200 minutes, most of them being around 100 minutes. ELT of chronic nasopharyngitis were longer than 200 minutes, mostly around 300 to 350 minutes and ELTs of subacute nasopharyngitis were in between. In other words there was characteristic difference in ELT between acute and chronic nasopharyngitis. ELT of subacute nasopharyngitis were similar to those of the normal subjects shown in Fig 33 and they might belong to either the acute or the chronic group.

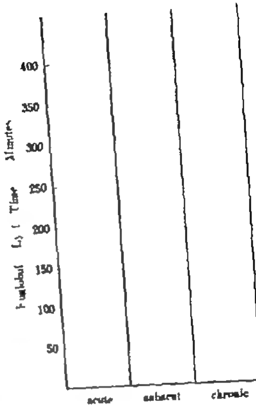

Fig. 33.

From these results it became clear that ELT changed according to the condition of nasopharyngeal inflammation. It was even more interesting to know that ELT changed after stimulating the nasopharynx as shown in Fig 34. ELT of blood taken before stimulation of nasopharynx was 175 minutes, but ELT determined 15 minutes after stimulation, which was performed immediately after blood taking, was shortened to 135 minutes and ELT recovered to

12 Nasopharyngeal Stimulation and Alteration of the Body Fluids

In the preceding paragraph it was mentioned that stimulation of the nasopharynx had significant influence on the autonomic nervous system It is well known that changes in the condition of the autonomic nervous system bring alteration of catecholamine cholin and various other body fluids. And it is easily supposed that alteration of various body fluids is also caused secondarily by this.

Considering these possibilities the author studied what influence nasopharyngeal stimulation had on the body fluids. From clinical necessity studies were first conducted on the following items.

1 Alteration of fibrinolytic activity
2 Alteration of plasma 11 OHCS
3 Alteration of γ-globulin
4 Alteration of free fatty acid in plasma

Putting aside how these are related to catecholamine cholin or the autonomic nerve center mentioned before, the experiments conducted on the above 4 items by the author are reported below

1) **Alteration of Fibrinolytic Activity**
Blood coagulates when it comes out of the body through bleeding If this coagulated clot is left as it is it starts to dissolve again after a while This phenomenon is called fibrinolysis of blood It is known that this phenomenon is accelerated by stress. When there is acute inflammation in the body or a rheumatic attack this fibrinolysis is accelerated If that is the case what kind of correlation exists between this fibrinolysis and the nasopharynx, in which an inflammatory condition is constantly found in many cases?

To study this the author determined the fibrinolysis of blood from patients with nasopharyngitis and those without nasopharyngitis (those with no significant inflammatory changes when nasopharyngeal tests were conducted) (In both groups only those who had never experienced nasopharyngeal treatment were used.) BUCKELL's method was used as shown below

1 0.5 ml of 0.1 ammonium oxalate solution and 4.5ml of blood were mixed.
2 Serum was separated by centrifuging the mixture at 3 000rpm for 5 minutes. The supernatant was discarded.
4 The precipitate was dissolved in 0.5ml of 0.5* borate buffer in a water bath keps at 37°C 0.5ml of 0 025M $CaCl_2$ was added to it to stimulate stimulate coagulation and the time needed for coagulation was determined.
5 The time needed for dissolution of the serum was determined.

As shown above Euglobulin Lysis Time (ELT) was determined Fig 32 shows the

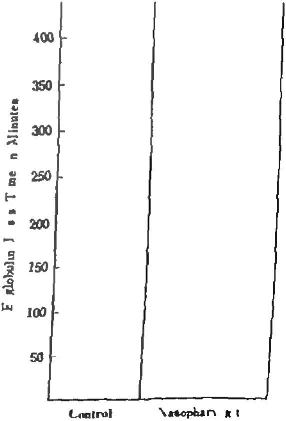

Fig. 32.

than in acute and subacute nasopharyngitis not only the decrease of ELT after 15 minutes was less but also its recovery was remarkable and it had already returned to close to the normal value after 90 minutes. On the contrary in acute nasopharyngitis, ELT was shortened significantly by stimulation, about 70% after 15 minutes, and only in a few cases was ELT restored to the level before stimulation after 90 minutes most ELT stayed at 70% to 80%.

What kind of factors caused such differences in ELT between acute and chronic nasopharyngitis is a serious problem and needs to be solved in the future. In acute nasopharyngitis, abrasion of the nasopharyngeal mucosa by a cotton applicator often caused severe pain, while in chronic nasopharyngitis it hardly caused pain. Therefore this difference in ELT between acute and chronic nasopharyngitis was possibly thought due to difference in stress, namely abrasion pain. When ELT was determined on treating after radical operation on the middle ear which was accompanied with severe pain, as a control, values like those obtained in acute nasopharyngitis were not necessarily obtained. This finding suggested that changes of ELT after stimulation of nasopharynx were not caused only by differences in abrasion pain.

When local treatment of an inflamed nasopharynx was performed, inflammation was cured relatively easily hemorrhage on abrasion disappeared after 1 to 2 weeks, abrasion pain disappeared after 2 to 3 weeks and smears also showed a normal picture. ELT at this stage, however showed significant difference when compared with that determined before the treatment. (For the treatment 1 to 2 % $ZnCl_2$ solution was applied to the nasopharynx every day or every other day. ELT was tested before and after application of 1 to 2 % $ZnCl_2$ solution. As the same treatment as that which has been performed everyday was performed before and after the ELT test habituation came into question. However when nasopharyngitis took a

Table 50 Fibrinolytic activity of one Case

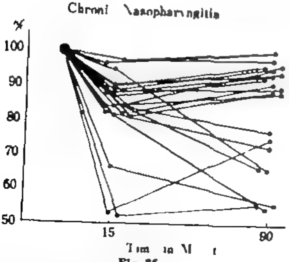

Fig 36.

160 minutes 90 minutes after stimulation The phenomenon that ELT was shortened temporarily after stimulation of the nasopharynx, was common to all susbject and ELT reached its minimum value about 15 minutes after stimulation of the nasopharynx and returned to the original value after 90 minutes or more. The minimum value obtained 15 minutes after stimulation and the state of recovery were different depending on the case when these were observed separately Figs. 35 36 and 37 show ELTs determined by stimulating the nasopharynx of the patients with acute chronic and subacute nasopharyngitis. Taking the value before stimulation as 100 ELTs 15 and 90 minutes after stimulation are shown in these figures, which show that the reaction of ELT to stimulation of the nasopharynx was different depending on the individual case

In chronic nasopharyngitis (Fig 36) the effect of stimulating the nasopharynx was less

serious turn because of a cold in spite of continuation of the treatment ELT also moved backwards. Therefore there seemed to be no habituation phenomenon.)

Typical ELT curves before and after the treatment of the nasopharynx were shown in *Table 30 and Fig 38.* In these cases ELT after the treatment became significantly longer compared to that before the treatment Those cases whose *ELT* was prolonged by the nasopharyngeal treatment has short ELT in other *words they had acute or subacute nasopharyngitis.* In chronic patients ELT was shortened or was not changed by the treatment Fig 39 showed *ELT* values 15 minutes after stimulation of nasopharynx in chronic patients. It was observed that there eas a tendency for ELT to remain at a constant value during the nasopharyngeal treatment

2) Alteration of Plasma 11 OHCS

It is a fact that rheumatism and allergy can be healed or improved very successfully only by local treatment of the nasopharynx Why has such an effect of nasopharyngeal treatment been elucidated yet? As mentioned before inflammatory foci always exist in the nasopharynx and this inflammation becomes severe in case of rheumatism or allergy Treatment of this inflammation runs parallel to treatment of these original diseases. In rheumatism, for example nasopharyngitis has the necessary and sufficient conditions to act as a source of focal infection and also in the incipient stage of nasal allergy or asthma an abnormal feeling in the nasopharynx appears first as a premonitory symptom And so it is most important to treat nasopharyngitis, which is one of the sources of these diseases, and to keep it from participating in their attack. It is very important to study their relation further for investigation of a mechanism of inflammation and allergy

To investigate the mechanism of causal relation between nasopharyngitis and these diseases, the relationships between nasopharyngitis and *ELT* and between nasopharyngitis and the autonomic nervous system have been studied and reported It is known that ELT is accelerated in proportion to aggravation of inflammation in case of rheumatism and a kind of abnormality in a mechanism of autonomic nerve has an important relation to acceleration or disappearance of inflammation.

It is also clear that an accelerated condition of ELT and an abnormal condition of the autonomic nerve and parallel to nasopharyngitis. The relation between nasopharyngitis and blood adrenocortical hormone was studied next

Urinary 17 KS and 17-OHCS are usually determined for an abnormal function test and *both methods require storage of* whole day urine It is necessary to observe blood steroids to study changes in excretion of adrenal hormone immediately after stimulation of the nasopharynx. Plasma 11-OHCS (11 Hydroxy corticosteroids) was chosen for the purpose

Hydrocortisone and corticosterone the main adrenocortical hormones in blood which emit fluorescence on reacting with sulfuric acid were determined by a fluorometer It was SWEAT (1954) that advocated the first determination of blood steroids by a fluorometer SWEAT's method was gradually improved and DE MOOR (1961) established a highly reliable *method.*

Determination Method

Ten ml of methylene chlorid were added to 2 ml of plasma, shaken for 30 seconds by hand and centrifuged at 3,000rpm for 7 minutes. One ml of 1/10 N NaOH was added to the methylene chloride layer

It was observed that there eas a tendency for FLT to remain at a constant value during the nasopharyngeal treatment

2) *Alteration of Plasma 11-OHCS*

It is a fact that rheumatism and allergy can be healed or improved very successfully only by local treatment of the nasopharynx Why has such an effect of nasopharyngeal treatment been elucidated yet? As mentioned before inflammatory foci always exist in the nasopharynx and this inflammation becomes severe in case of rheumatism or allergy Treatment of this inflammation runs parallel to treatment of these original diseases. In rheumatism for example, nasopharyngitis has the necessary and sufficient conditions to act as a source of focal infection, and also in the incipient stage of nasal allergy or asthma an abnormal feeling in the nasopharynx appears first as a premonitory symptom. And so it is most important to treat nasopharyngitis, which is one of the sources of these diseases, and to keep it from participating in their attack. It is very important to study their relation further for investigation of a mechanism of inflammation and allergy

To investigate the mechanism of causal relation between nasopharyngitis and these diseases, the relationships between nasopharyngitis and ELT and between nasopharyngitis and the autonomic nervous system have been studied and reported It is known that ELT is accerlated in proportion to aggravation of inflammation in case of rheumatism and a kind of abnormality in a mechanism of autonomic nerve has an important relation to acceleration or disappearance of inflammation.

It is also clear that an accelerated condition of ELT and an abnormal condition of the autonomic nerve and parallel to nasopharyngitis. The relation between nasopharyngitis and blood adrenocortical hormone was studied next

Urinary 17 KS and 17-OHCS are usually determined for an abnormal function test and both methods require storage of whole day urine It is necessary to observe blood steroids to study changes in excretion of adrenal hormone immediately after stimulation of the nasopharynx. Plasma 11-OHCS (11 Hydroxycorticosteroids) was chosen for the purpose

Hydrocortisone and corticosterone the main adrenocortical hormones in blood which emit fluorescence on reacting with sulfuric acid were determined by a fluorometer It was SWEAT (1954) that advocated the first determination of blood steroids by a fluorometer SWEAT's method was gradually improved and De Moor (1961) established a highly reliable method

Determination Method

Ten ml of methylene chlorid were added to 2 ml of plasma, shaken for 20 seconds by hand and centrifuged at 3 000rpm for 7 minutes. One ml of 1/10 N NaOH was added to the methylene chlorid layer

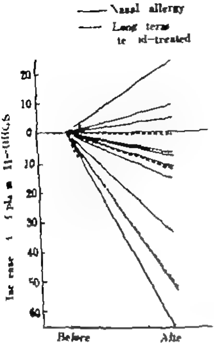

Fig. 43. Nasal allergy and long term steroid-treated cases (18 cases)

after the stimulation were calculated taking that before the nasopharyngeal stimulation as 0 The same data shown in Fig. 40 were used. Even in this figure change rates increased significantly after the stimulation in some subjects, while decreasing in others. Remarkable distinctions were found, however by applying these increasing and decreasing cases to cases of nasopharyngitis. These 53 subjects were divided into 2 groups, namely 35 subjects suffering simply from nasopharyngitis (Fig 42) and 18 subjects with nasal allergy or who had been taking steroids for a long term (Fig 43) and a remarkable difference was observed by comparing these 2 groups.

In subjects with only nasopharyngitis, plasma 11-OHCS increased in all cases after stimulation of the nasopharynx and reached +133% or +220% in some subjects, while in subjects taking steroids or with nasal allergy plasma 11-OHCS after nasopharyngeal stimulation did not change, or rather decreased. Plasma 11 OHCS increased more significantly in the subjects with more severe inflammation in the nasopharynx, as in Fig 42. However in the subjects with nasal allergy or who had been taking steroids for a long term plasma 11 OHCS decreased after stimulation of the nasopharynx in spite of their having severe nasopharyngitis. This fact seemed to show that the mechanism of steroid excretion, the mechanism of ACTH excretion or that of CRF excretion from the hypothalamus was weakened.

As plasma 11-OHCS was altered easily (De Moor, 1960, 1962 Bliss, 1953) it was necessary to observe changes of plasma 11-OHCS for 15 minutes without any nasopharyngeal stimulation as a control. Table 32 and Fig 44 were prepared for this reason. In the subjects shown in Fig 41 42 and 43 the nasopharynx was stimulated between 2 blood-drawings, while in the subjects shown in Table 32 and Fig 44 blood was taken after 15 minutes without nasopharyngeal stimulation. Values of 11-OHCS varied also in Fig 44 but they chenged little during the 15 minutes. The mean and standard deviation of 11-OHCS after 15 minutes was $-8 \pm 9.4\%$ which showed a slight decrease. Therefore it could be said that 11-OHCS hardly changed or rather decreased during the 15 minutes when the nasopharynx was not

Table 32 Plasma 11-OHCS concentration (γ/dl) without stimulation

Case	Name	Age	Sex	Before	After	Differ	Rate ( )
1	A.Y	19	M	23.1	21.2	−1.9	− 8
2	Y M.	23	M	24.1	22.2	−1.9	− 8

5	A.A.	24	F	10.9	7.8	−3.1	−28
6	M.M.	20	[illegible]	6.1	6.1	0	0
Mean				17.4	16.0	−1.4	− 8 ± 9.4

Measured between 3-4 p.m.

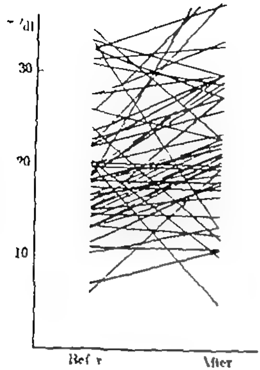

Fig. 40. Plasma 11-OHCS after stimulation of the nasopharynx (53 cases)

the bottom layer which was shaken for 15 seconds, while the upper NaOH layer was removed completely. The methylene chloride layer was washed one more time with 1/10 N NaOH. The same procedure was conducted on both blank and standard reagents.

Five ml of a reagent (70% sulfuric acid in ethanol) were added to the extract thus obtained, shaken for 30 minutes by hand and the upper methylene chloride layer was removed. The bottom sulfuric acid ethanol layer was tested by a fluorometer.

Fluorescence was determined exactly 15 minutes *after adding the reagent.*

The author determined plasma 11-OHCS by the above method and studied whether 11-OHCS was changed by the nasopharyngeal stimulation (YAMADA, 1972). As plasma 11-OHCS changes easily, the author made every possible effort to catch changes caused by the nasopharyngeal stimulation if there were any. By actually measuring plasma 11-OHCS of 53 subjects before and 15 minutes after the stimulation of nasopharynx, the author got the data shown in Table 31 and Fig. 40 which were so variable that they could not be controlled. Plasma 11-OHCS before and after the stimulation of nasopharynx changed in some subjects, did not change in others, increased in some subjects and decreased in others. So as shown in Fig. 41, the change rates of plasma 11-OHCS

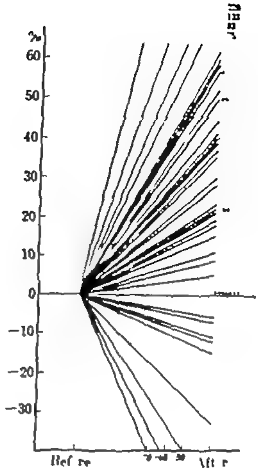

Fig. 41. Plasma 11-OHCS after stimulation of nasopharynx (53 cases)

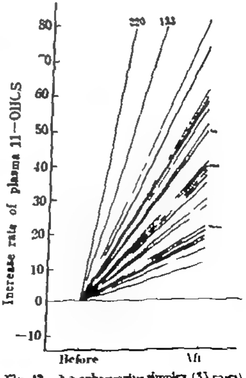

Fig. 42. Nasopharyngitis simplex (53 cases)

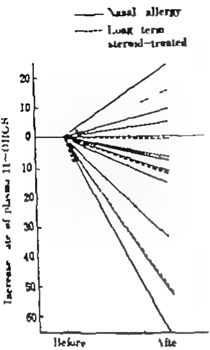

Fig. 43. Nasal allergy and long term steroid-treated cases (18 cases).

after the stimulation were calculated taking that before the nasopharyngeal stimulation as 0. The same data shown in Fig 40 were used. Even in this figure change rates increased significantly after the stimulation in some subjects, while decreasing in others. Remarkable distinctions were found, however by applying these increasing and decreasing cases to cases of nasopharyngitis. These 53 subjects were divided into 2 groups, namely 35 subjects suffering simply from nasopharyngitis (Fig 42) and 18 subjects with nasal allergy or who had been taking steroids for a long term (Fig 43) and a remarkable difference was observed by comparing these 2 groups.

In subjects with only nasopharyngitis, plasma 11-OHCS increased in all cases after stimulation of the nasopharynx and reached +133 or +220% in some subjects, while in subjects *taking steroids or* with nasal allergy plasma 11-OHCS after nasopharyngeal stimulation did not change, or rather decreased. Plasma 11 *OHCS increased more significantly* in the subjects with more severe inflammation in the nasopharynx, as in Fig 42. However in the subjects with *nasal allergy or who had been* taking steroids for a long term, plasma 11 OHCS decreased after stimulation of the nasopharynx in spite of their having severe nasopharyngitis. This fact seemed to show that the mechanism of steroid excretion the mechanism of ACTH excretion or that of CRF excretion from the hypothalamus was weakened.

As plasma 11-OHCS was altered easily (De Moor, *1960, 1962 Bliss, 1953*) it was necessary to observe changes of plasma 11-OHCS for 15 minutes without any nasopharyngeal stimulation as a control. Table 32 and Fig 44 were prepared for this reason. In the subjects shwon in Fig 41 42 and 43 the nasopharynx was stimulated between 2 blood-drawings, while in the subjects shown in Table 32 and Fig 44 blood was taken after 15 minutes without nasopharyngeal stimulation. Values of 11-OHCS varied also in Fig 44 but they chenged little during the 15 minutes. The mean and standard deviation of 11-OHCS after 15 minutes was −8± 9.4%, which showed a slight decrease. Therefore it could be said that 11-OHCS hardly changed or rather decreased during the 15 minutes when the nasopharynx was not

Table 32 Plasma 11-OHCS concentration (γ/dl) without stimulation

stimulated.

In simple nasopharyngitis, 11-OHCS increased immediately after stimulating the nasopharynx as shown in Fig 42. What was the the extent of this increase?

In Fig 45 the nasopharyngitis was roughly divided into 3 groups, namely slight, moderate and severe, and increasing rates of 11-OHCS in each group were shown. It was found that increasing rates of 11 OHCS were higher in marked nasopharyngitis. This increase might come from the stress, as abrasive pain was severer in marked nasopharyngitis than in slight cases. However YAMADA (1970 1972) conducted various control experiments and ruled against this possibility. In the subjects with nasal allergy (dotted line) and those who had used steroids for a long term (broken line) 11 OHCS decreased after the stimulation, showing no connection with the condition of nasopharyngitis, which was probably due to lowering of adrenocortical and pituitary functions. This phenomenon seems to be interesting material for explaining the mechanism of getting allergy

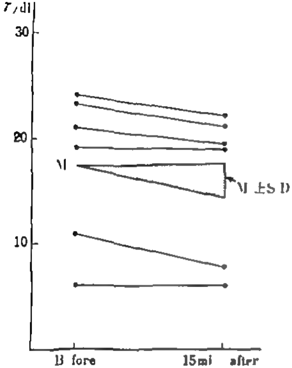

Fig 44. Plasma 11-OHCS concentration without stimulation.

Cessation of Long-term Steroid Treatment after Treating Nasopharyngitis

In the preceding chapter it was mentioned that blood 11 OHCS decreased immediately after stimulating the nasopharynx in those subjects who had been taking steroids for a long

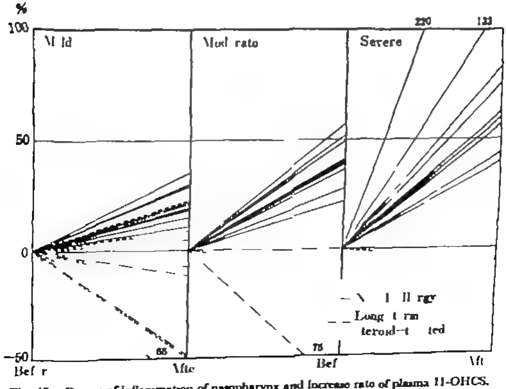

Fig 45. Degree of inflammation of nasopharynx and increase rate of plasma 11-OHCS.

term. This was observed typically in the patients with the so-called moon faces suffering from the side effects of steroids and having difficulties in withdrawing from steroids. When nasopharyngeal treatment was conducted on the patients with rheumatism, arthralgia and swelling of the joints disappeared, and RA and ASLO were improved as if steroids were administered. Therefore nasopharyngeal treatment was tried on the above-mentioned patients suffering from the side effects of steroids for the purpose of aiding their withdrawal from the steroids. It was found that various symptoms of rheumatism were improved and no more rheumatic fits were observed after stopping steroid administration and switching to nasopharyngeal treatment. Toxic symptoms of steroids were improved gradually and 11-OHCS after the stimulation, which was (−) before the treatment, increased gradually and was restored to its normal value.

Fig. 46 shows patients with rheumatism suffering from the side effects of steroids, for whom steroid administration was stopped and nasopharyngeal treatment was given instead.

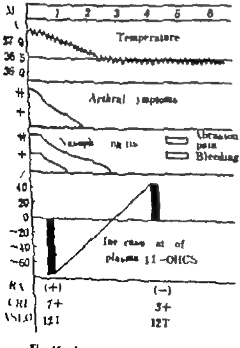

Fig. 46. Long term steroid-treated Case. H.U. 17y m, F. Rheumatoid arthritis.

Slight fever and joint symptoms had almost disappeared 2 months after starting the treatment. 11-OHCS measured at the beginning of the treatment was −80%, however increased to +40% after 4 months. Severe abrasive pain and bleeding after abrasion were observed at the beginning, but the bleeding stopped after about 1 month and abrasive pain disappeared after 3 months. As could be seen in these patients, the following facts were found when steroids were taken for a long term.

1. Excretion of 11-OHCS after the nasopharyngeal stimulation was decreased.
2. After stopping nasopharyngeal treatment and steroid administration, plasma 11-OHCS after the nasopharyngeal stimulation gradually came near its normal value.

It is generally said that an operation during steroid administration is dangerous as it may cause a shock and when steroid administration is stopped suddenly life may be in danger. Considering this fact together with the phenomenon that excretion of steroids decreased immediately after stimulation of the nasopharynx, it seems more probable that excretion of steroids decreases because of stimulation by stress rather than that steroids are not excreted sufficiently when a living body is stressed. It is important to determine whether this decrease of plasma 11-OHCS after the stimulation occurs simply as a related phenomenon or whether the decrease of steroids itself is directly related to the shock. However it is not known which is the case.

When nasopharyngeal treatment is conducted on the patients with difficulty in withdrawing from steroids, steroids are withdrawn relatively easily in many cases (In some cases it is improved on the day when the treatment is started.) The mechanism, however is not clear yet. Since excretion of steroids decreased after nasopharyngeal stimulation.

1. The mechanism of attacks, which were suppressed by nasopharyngeal treatment, might not be related to steroids.

2. Since observations were conducted for 15 minutes after stimulation of the nasopharynx in this study the phase, where excretion of steroids in blood was increased, might be seen by observing for a longer term.

These problems will be solved by continuing

stimulated

In simple nasopharyngitis 11-OHCS increased immediately after stimulating the nasopharynx as shown in Fig 42 What was the the extent of this increase?

In Fig 45 the nasopharyngitis was roughly divided into 3 groups, namely slight moderate and severe and increasing rates of 11-OHCS in each group were shown It was found that increasing rates of 11-OHCS were higher in marked nasopharyngitis. This increase might come from the stress, as abrasive pain was severer in marked nasopharyngitis than in slight cases. However YAMADA (1970 1972) conducted various control experiments and ruled against this possibility In the subjects with nasal allergy (dotted line) and those who had used steroids for a long term (broken line) 11 OHCS decreased after the stimulation, showing no connection with the condition of nasopharyngitis, which was probably due to lowering of adrenocortical and pituitary functions. This phenomenon seems to be interesting material for explaining the mechanism of getting allergy

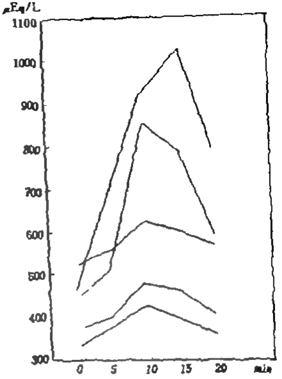

Fig. 48. Change of plasma FFA after nasopharynx stimulation.

period and external stimulations were a oided as much as possible.

Serum was kept in refrigerator immediately after its separation. Determination of FFA was conducted 3 to 4 hours afte blood drawing.

Spontaneous Changes of FFA in Plasma

I was mentioned before that FFA in blood is altered by arious factors. It is said that FFA in blood increases gradually w th hunger as blood ugar decreases. Spontaneous changes of plasma FFA *were tested on 3 subjects and it was* found that FFA changed little between 0 and 20 minutes as show in Fig. 47. In other words it was confirmed that FFA did ot hange during 20 minutes, which was necessary for th next step, unless special treatments were gi en.

Ultration of Plasma FFA with Time after Naso-pharyngeal Stimulation

Nasopharyngeal irritation has as much ffect on the tonomic nerv *as stress, and it is quite* possible that plasma FFA changes by naso-pharyngeal stimulation.

Therefore how plasma FFA changed with time after nasopharyngeal stimulation was studied.

Blood was taken 5 times, namely before stimulation, 5 minutes, 10 minutes, 15 minutes and 20 mun tes after stimulation and FFA in the plasma specimens from 5 subjects was deter mined (Fig. 48). As shown in Fig. 48, it was found that plasma FFA increased significantly after nasopharyngeal stimulation. *A peak was reached 10 minutes after nasopharyngeal stimulation in 4 subjects, 15 minutes after stimulation* in 1 subject, and then plasma FFA decreased gradually to the value before stimulation.

The average increasing rate after 10 minutes was 54±38.2% in 5 subjects and after 20 minutes it was 23. These values were quite different from the increasing rates of spontaneous changes in 10 and 20 minutes, which were 2.2±2.3 and 4.4±0.8% respectively. This *fact suggested that plasma FFA responded to* nasopharyngeal stimulation sensitively through *adreno-sympathetic control.*

Increasing Rates of Plasma FFA in the Patient

this study further but it is certain that nasopharyngeal treatment improves most rheumatisms and allergies as administered steroids do

By what kind of mechanism does plasma 11 OHCS decrease immediately after stimulating the nasopharynx of the patients who have been taking too much steroids?

ACTH from the pituitary is necessary for excretion of steroids in blood and for this stimulation CRF (Corticotropin Releasing Factor) from the hypothalamus is necessary It is not known how the nasopharyngeal stimulation affects this pathway However it can be imagined that the stimulation of the nasopharynx affects directly the hypothalamus. For example, in disfunction of the thyroid gland nasopharyngeal treatment normalized basal metabolism effectively in some cases and a similar fact was also observed in the liver function. From this finding it is presumed that stimulation or treatment of the nasopharynx stimulates the hypothalamus or corrects disfunction of the hypothalamus and normalizes abnormal conditions of various organs via the hypothalamus. It is also presumed that stimulation of the nasopharynx or treatment of its inflammation affects centers of the autonomic nerve system such as the hypothalamus

Further experiments are needed to show whether decrease in excretion of 11 OHCS by stimulation of the nasopharynx results from atrophy of the adrenal cortex or from temporary malfunction Judging from the fact that 11 OHCS which was decreased after the stimulation easily recovered after nasopharyngeal treatment, it can be thought that decrease in the function of the adrenal cortex was only temporary at least in our subjects It is often observed by autopsy that patients who used to take too much steroids, have an adrenal cortex as thin as a sheet of paper Can such an atrophied adrenal cortex be treated so easily by discontinuing steroids and stimulating the nasopharynx, or is nasopharyngeal treatment not effective in such patients? These questions are left to be answered

3) **Alteration of γ globulin** (Will be treated later)

4) **Alteration of Free Fatty Acids in Plasma**

Free fatty acids (FFA) in plasma are altered by various factors. For example glucose prevents their emigration while growth hormone ACTH adrenalin and noradrenalin accelerate their emigration It is known that FFA in plasma quickly changes under adreno-sympathetic control, and their change can be prevented by administering autonomic nerve blocking agents beforehand Therefore by observing the change of FFA in plasma caused by nasopharyngeal stimulation we can surmise how change of adreno-sympathetic control takes place.

Procedure for Determination (Improved DUNCAN's Colorimetric Method)

0 4 ml of serum was pipetted into a centrifuge tube with a stopper and 6.0 ml of chloroform and 2 0 ml of copper nitrate reagent were added. The mixture was shaken vigorously and centrifuged at 2,500 rpm for 5 minutes. The supernatant was removed completely by an aspirator 3 0 ml of the remaining chloroform layer was transfered to a test tube with a stopper 1 0 ml of a color reagent was added mixed well and let stand for 15 minutes at room temperature. The optical density of the solution was measured with a photoelectric colorimeter against a blank. The optical density of a standard solution was obtained by processing 1 mEq/l of palmitic acid in the same way FFA in blood was calculated according to the following equation

$$\frac{E(A)}{E(S)} = \text{mEq FFA/l}$$

E(A) = Optical density of the sample

E(S) = Optical density of the standard solution

Though the amount of FFA in plasma is very small compared to other lipids, it changes rapidly in plasma. As FFA in plasma is apt to be affected by various metabolic systems, the conditions of determination have to be kept constant and other effects have to be diminished as much as possible.

Patients fasted after having supper the night before and visited the hospital at 9 a m After lying quietly on a bed for about 30 minutes, blood was taken from an elbow vein and the nasopharynx was stimulated immediately after The patients lay quietly on a bed during this

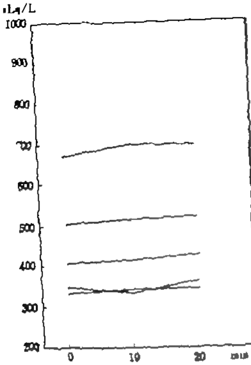

Fig. 47. Plasma FFA concentration without stimulation.

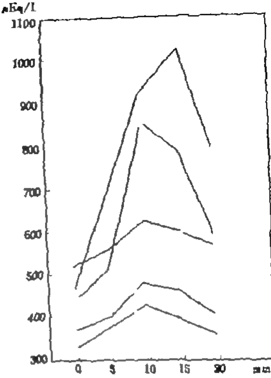

Fig. 48. Change of plasma FFA after nasopharynx stimulation.

period and external stimulations were avoided as much as possible.

Serum was kept in a refrigerator immediately after its separation. Determination of FFA was conducted 3 to 4 hours after blood drawing.

Spontaneous Changes of FFA in Plasma

It was mentioned before that FFA in blood is altered by various factors. It is said that FFA in blood increases gradually with hunger as blood sugar decreases. Spontaneous changes of plasma FFA were tested on 5 subjects and it was found that FFA changed little between 0 and 20 minutes as shown in Fig. 47. In other words it was confirmed that FFA did not change during 20 minutes, which was necessary for the next step, unless special treatments were given.

Alteration of Plasma FFA with Time after Nasopharyngeal Stimulation

Nasopharyngeal irritation has as much effect on the autonomic nervous system, and it is quite possible that plasma FFA changes by nasopharyngeal stimulation.

Therefore how plasma FFA changed with time after nasopharyngeal stimulation was studied.

Blood was taken 5 times, namely before stimulation, 5 minutes, 10 minutes, 15 minutes and 20 minutes after stimulation and FFA in the plasma specimens from 5 subjects was determined (Fig. 48). As shown in Fig. 48 it was found that plasma FFA increased significantly after nasopharyngeal stimulation. A peak was reached 10 minutes after nasopharyngeal stimulation in 4 subjects, 15 minutes after stimulation in 1 subject, and then plasma FFA decreased gradually to the value before stimulation.

The average increasing rate after 10 minutes was 34 ± 38.2* in 5 subjects and after 20 minutes it was .3. These values were quite different from the increasing rates of spontaneous changes in 10 and 20 minutes, which were 2.2 ± 2.3 and 4.4 ± 0.8 respectively. This fact suggested that plasma FFA responded to nasopharyngeal stimulation sensitively through adreno-sympathetic control.

Increasing Rates of Plasma FFA in the Patients

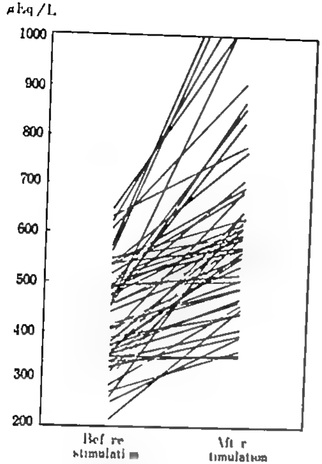

Fig. 49 Change of plasma FFA before and after stimulation (At first visit)

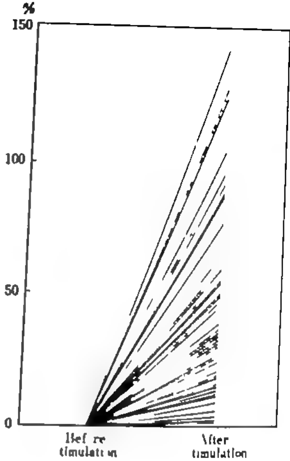

Fig. 50. Increase rate of plasma FFA after stimulation of the nasopharynx (At first visit)

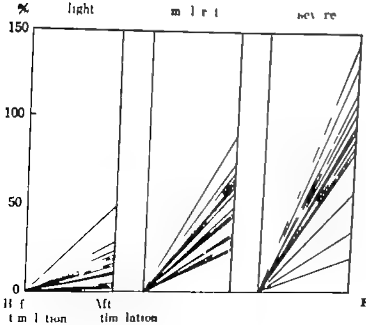

Fig. 51 Degree of inflammation of the nasopharynx and increase rate of plasma FFA.

with Nasopharyngitis

As mentioned previously plasma FFA hardly changed between 10 and 20 minutes when the nasopharynx was not stimulated.

Figs. 49 and 50 show plasma FFA determined immediately before and 10 minutes after nasopharyngeal stimulation at the first medical examination of 50 patients diagnosed as having nasopharyngitis. As plasma FFA changes by the effect of various metabolic systems, plasma FFA of the same subject varies when the conditions of determination change. However the change was very slight as shown in Fig. 47 when taking time difference (10 minutes) of 2 determinations (before and after stimulation) (Compare Figs. 47 and 48.) In nasopharyngeal stimulation, it could be observed that plasma FFA increased in 48 out of 50 subjects as shown in Figs. 48, 49 and 50. Its increasing rate extended over a wide range (1–142%) and no change was observed in 2 subjects.

Relation between the degree of nasopharyngeal inflammation and plasma FFA was studied next. It was found that there was a correlation between the degree of inflammation and the increasing rate of plasma FFA. This was similar to the case of 11-OHCS reported in the preceding chapter.

Increasing rate of plasma FFA in the patients with slight nasopharyngitis was $15 \pm 13.2\%$, 48 ± 18.7 in the patients with moderate nasopharyngitis and 88 ± 32.9 in those with marked nasopharyngitis (Fig. 51).

Improvement of Nasopharyngitis and Increasing Rate of Plasma FFA

It was studied how increasing rates of plasma FFA changed according to the treatment of nasopharyngitis.

Among 50 cases, changes were observed in 26 cases. The treatment period was 2 weeks in the shortest case, 1 to 2 months in most cases and some patients were treated for over a year. With a few exceptions where treatment was discontinued before complete recovery, satisfactory effect was observed in 24 out of 26

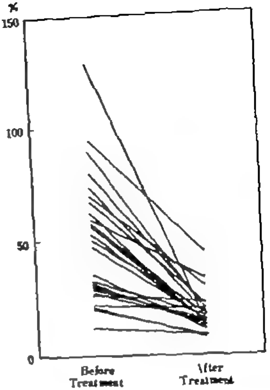

Fig. 52. Increase rate of plasma FFA after improvement of nasopharyngitis.

patients. When increasing rates of plasma FFA were determined at this stage, the values decreased in all cases compared to those at the first medical examination and were between 10 and 30% in 20 out of 26 patients (76%) as shown in Fig. 52. From these results it can be said that increasing rates of plasma FFA show not only the degree of nasopharyngitis but also the course of recovery of the inflammation and the reaction of the autonomic nerve against stress, the stimulation of the nasopharynx. In other words, an abnormal reaction, which is observed in sudden increase of plasma FFA, is controlled by nasopharyngeal treatment and this is supposed to show that nasopharyngeal treatment plays a role as a kind of homeostasis to correct an overreaction of the body.

Part II

Clinical Aspects of Nasopharyngitis

Nasopharyngitis is a latent inflammatory focus which exists in a large number of people. The presence of the inflammatory focus can be confirmed by examining smears obtained from the nasopharyngeal mucosa and its course can be accurately detected. The local treatment of nasopharyngitis shows interesting clinical phenomena along with alleviation of the inflammation. In the following pages the author will discuss the clinical observations in due order.

1 Significance of the Presence of Latent Inflammatory Focus in Nasopharyngitis

The presence of a latent inflammatory focus in the nasopharynx of majority of people is meaningful in various ways. Among these, the focal infection is an important characteristic of nasopharyngitis. Focal infection, like tonsillitis in rheumatism, had been assumed by many investigators as the basis of the hypothesis that its focus might act as the origin of various diseases. Nevertheless, not many inflammatory foci were found to become source of infection, just as tonsillitis was not always detected in rheumatic patients. This is true also regarding the theory of prolonged sensitization of OKABAYASHI.

OKABAYASHI (1963) observed prolonged sensitization after repeated forced infection in animals, which finally developed a kind of autoimmune disease and succeeded in producing autoimmune diseases like SLE or rheumatism. The results of the experiments were considered transferrable to human data, but clinicians failed to confirm the presence of chronic focal infection except in a few cases of tonsillitis. Thus the assumption of a chronic focal infection could not demonstrate the relationship between the focus and the onset of SLE or rheumatism, as successfully observed in animal experiments. We consider that autoimmune disease including the so-called collagen disease (in which autoantibody is not always detected) is closely related to existence of the inflammatory focus called nasopharyngitis through many clinical experiments. To demonstrate such relation is quite simple.

1. To examine the nasopharynx of the patients with autoimmune disease or collagen disease and confirm the presence of inflammation.
2. If nasopharyngitis is confirmed, employ a simple medication (1% $ZnCl_2$) and apply it with a cotton applicator into the nasopharynx and observe the response to the manifested diseases.
3. The local treatment as such is equal to artificial sounding of the infectious focus. In this we can observe the effect of the nasopharyngeal treatment in parallel to the clinical course of the manifested diseases.

1) Rheumatism

In the following chapters we will discuss the possibility of focal inflammation provoking autoimmune diseases such as rheumatism. Rheumatism may be classified into chronic *rheumatoid arthritis and rheumatic fever* and both of these are closely related to nasopharyngitis. *Clinically rheumatism is always associated with* intense nasopharyngitis and the *local treatment* can bring its cure or improvement.

Fig 53. Case No. 1 U T 32 Y o. F

Case No 1 (Fig 53)

U T A 32 year old female with rheumatic fever

Chief complaints A pain in the nasopharynx and in the knee joint

History No specific diseases were recorded in her family

In March 1965 she had pain in the throat with fever of 40 C which continued for 10 days. Since then she was susceptible to cold and often attacked by fever of 40 C with a prodromal symptom of the pain in the throat She visited an internist but she did not get well In February 1967 she had a similar attack and complained of pa n in the knee joint. She suffered from unlocalized pain in other places of the body also.

In March 1967 she was diagnosed as ha ng rheumatic fever by one of our colleagues. She had a normal temperature of about 37 C

Labor tory finding

ECG within normal range Chest X-ray was normal.

Blood sedimentation, 30 –45mm. 1 00–91mm. 2°00–140mm.

Serum ASL-O values, 625 T U

CRP ### RA (+)

Diagnosis After close examination at the medical department of this university rheumatic fever was indicated.

Nasopharynx. A marked abrasion pain (#) and abrasion hemorrhage (+) were observed. The nasopharyngeal abrasion preparation revealed a markedly ntense exfoliation and transformation of ciliated epithelial cells and a large number of treptococci iridans and Gram negati e diplococci were identified. Sl ght hypertrophy of th palatin tonsil was observed, but no inflan mation existed

Clinical course of nasopharyngitis. Clinical course after in tial examination is shown Fig 53. All medications were discontinued except the local treat ent of nasopharyngitis. Th local inflammation n the nasopharyn wa intense and resisted the treatment. The post bras e hemorrhage continued for bout 40 days. (Usually bleeding terminates in 10–14 days.) Abrasion pain finally disappeared after

three months of treatment. (Simultaneous disappearance of inflammation was obtained.) (Generally abrasion pain disappears in 1 3 weeks in parallel to alleviation of inflammation.)

The patient fever dropped to normal state (Below 37.5°C constantly.) It took long time to completely cure the disease (6 months of daily treatment) Also it took about one year until the serum ASLO alues returned to normal. (The last column of diagram.) The rise and fall of bacterial flora is also shown in the diagram. Non toxic staph. epidermis appeared only after normalization of serum alues. The diagram also indicates prolonged contraction period of pulse w of the fingertip (The Basic Study of Nasopharyngitis). Measurement of the pulse w was intended to examine how rheumatism affects the autonomic nerves of the peripheral site, but this may be observed ir respecti of the presence of rheumatism. As above case of rheumatic fever was studied. From that you can see that complete cur requires local treatment for long period. The case which lead to complete heal has few relapses, if any will be easily cured by the local treatment.

Case No. 2 (Fig. 54)

H.T A 22 year old male with chronic rheumatic arthritis.

Chief complaint Pain in bilateral knee joints.

History The pain attacked his right knee joint after work. It reached both knee joints and the gait was disturbed. H isited an arthopedic clinic and was diagnosed as ha ing chronic arthritis. In spite of arious medications he did

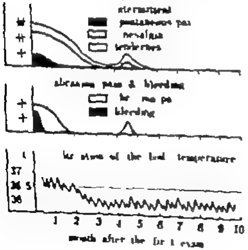

Fig. 54. Case No. 2) *Clinical course of typical case.* H.T 22 y o. M.

not get well. In winter besides the knee joints, he felt pain and swelling in the achilles tendon. He then felt pain in the right shoulder or in both ankles. Various treatments were tried but in vain.

Clinical findings ECG remained normal, erythrocyte sedimentation

30'–5mm.
1 10mm.
2 –10mm.

Serum ASLO 166 T U CRP ++ RA (−)

Temperature At time of admission to the hospital, the fever ranged around 37°C.

Diagnosis After intensive examination by an orthopedic surgeon, the patient was diagnosed as having chronic rheumatoid arthritis.

Nasopharyngitis Routine ORL examination failed to detect abnormality in the nasopharynx but application of a cotton pplicator dipped in 1% $ZnCl_2$ at the dorsal surface of soft palate caused severe abrasion pain and bleeding which ran dow through the wall of the nasopharynx. I tense erosion and marked inflammation were observed at the back of the soft palate. The smear preparation indicated a large amount of exfoliated and transformed ciliated epithelial cells and emigration of leucytes. A large number of streptococci viridans and staphylococci aureus were observed. It must be noted that the patient had no subjecti symptoms in the nasopharynx and routine ORL examination failed to detect abnormality but so intense, severe inflammation was present. Such phenomenon is general pictur of nasopharyngitis and it is the reason why the nasopharyngitis had been missed by the medical profession.

Clinical course Patient response to the treatment is shown in Fig. 54.

Postabrasion hemorrhage as esult of the nasopharyngeal treatment was persistent for about one month and the abrasion pain continued for two months. A slight fever was observed for the first one month but he returned to normal in three months. Since commencement of the treatment all other medications and treatments had been discontinued. In response to the treatment, the inflammation was reduced and at the same time rheumatic symptoms gradually disappeared. The spontaneous pain in the joints disappeared in one to fi months, and the kinesalgia and tenderness were improved in three months. The patient felt slight stiffness in the ankle joint or achilles tendon early in the morning and after exercise. In the fourth month he caught cold again and the pain attacked both knees. Abrasion pain and post abrasi bleeding were observed. The smear preparation indicated exacerbation of the inflammation. After two to three days of the

local treatment he got well. Disappearance of the symptoms brought disappearance of the local inflammation. After continuous treatment C.R.P became negative in four months and the bacterial flora inactive (negative) The nasopharyngeal treatment with 1 $ZnCl_2$ had been continued for about one year every other day or twice weekly At the end of the year it was carried out once a week. (Since the treatment was experimental, the same method had been employed throughout the period.) No recurrence was observed in this patient after being cured

Treatment of Rheumatism as a Complication of Nasopharyngitis

As mentioned previously moderate to severe nasopharyngitis without manifest subjective symptoms has been detected in 80 % of normal persons, but a latent inflammatory focus always exists in rheumatic patients. Table 33 shows the results of the examinations in 14 randomly selected cases.

The patients with rheumatism were treated for nasopharyngitis in our ORL clinic and 15 cases of chronic arthritis and 9 cases of rheumatic fever were selected for the study All other medications were discontinued except the local treatment of nasopharyngitis with 1 $ZnCl_2$ solution and the patients response to the treatment are indicated in Table 34

Assessment of clinical results was carried out in accordance with the following criteria.

Table 33 Grade of inflammation of nasopharyngitis in rheumatic cases.

	Improved	7 cases
	Rather improved	6 cases
	Unchanged	5 cases
2)	9 cases of rheumatic fever	
	Cured	6 cases
	Improved	3 cases
	Unchanged	0

Cured — No appearance of arthritic symptoms for over three years. (Informal cases for over 3 years) Disappearance of objective symptoms of arthritis and normal temperature has been maintained Improvement of serum reaction.

Improved — Alleviation of arthritic symptoms as compared with those before treatment and recovery to normal activity Attainment of lowering of the body temperature Serum levels unsatisfactory

Unchanged — No improvement has been attained in arthritic symptoms and other clinical findings.

Certain cases did not pass three years from commencement of the treatment Some were transferred from the improved group to the cured group

Degrees of chronic rheumatoid arthritis are classified according to the Steinbrocker classification into grades I II and III In the grade I group a considerable number of complete cures could be seen but in grades II and III good results could not be expected and especially the patients of grade III with deformed joints did not respond to the treatment Alleviation of pain was the best result we could expect in these patients.

In contrast patients belonging to grade I responded fairly well to the treatment As shown in Table 35 five out of 11 were cured Most of them maintained a normal state for a long time As shown in Table 36, favorable answers were returned to us from the patients who were cured three years ago

As shown in Table 37 we studied 9 cases of rheumatic fever Some of them showed a good response to the treatment in one month but

most of them had to be treated for five to six months. In these cases, like chronic rheumatoid arthritis, the treatment was nothing but an application of 1% $ZnCl_2$ to the inflammatory site. To our regret, these patients were mild cases with normal ECG (though some had slight ECG abnormality but soon recovered after the nasopharyngeal treatment).

We observed that all cases of chronic rheumatoid arthritis and rheumatic fever exhibited

local treatment he got well Disappearance of the symptoms brought disappearance of the local inflammation. After continuous treatment C.R.P became negative in four months and the bacterial flora inactive (negative) The nasopharyngeal treatment with 1 $ZnCl_2$ had been continued for about one year every other day or twice weekly At the end of the year it was carried out once a week. (Since the treatment was experimental, the same method had been employed throughout the period.) No recurrence was observed in this patient after being cured

Treatment of Rheumatism as a Complication of Nasopharyngitis

As mentioned previously moderate to severe nasopharyngitis without manifest subjective symptoms has been detected in 80% of normal persons, but a latent inflammatory focus always exists in rheumatic patients. Table 33 shows the results of the examinations in 14 randomly selected cases

The patients with rheumatism were treated for nasopharyngitis in our ORL clinic and 15 cases of chronic arthritis and 9 cases of rheumatic fever were selected for the study All other medications were discontinued except the local treatment of nasopharyngitis with 1 % $ZnCl_2$ solution and the patients response to the treatment are indicated in Table 34

Assessment of clinical results is carried out in accordance with the following criteria

Cured — No appearance of arthritic symptoms for over three years.

Table 33 Grade of inflammation of nasopharyngitis in rheumatic cases.

(Informal cases for over 5 years) Disappearance of objective symptoms of arthritis and normal temperature has been maintained Improvement of serum reaction.

Improved — Alleviation of arthritic symptoms as compared with those before treatment and recovery to normal activity Attainment of lowering of the body temperature. Serum levels unsatisfactory

Unchanged — No improvement has been attained in arthritic symptoms and other clinical findings.

Certain cases did not pass three years from commencement of the treatment. Some were transferred from the improved group to the cured group

Degrees of chronic rheumatoid arthritis are classified according to the Steinbrocker classification into grades I II and III In the grade I group a considerable number of complete cures could be seen, but in grades II and III good results could not be expected and especially the patients of grade III with deformed joints did not respond to the treatment Alleviation of pain was the best result we could expect in these patients

In contrast patients belonging to grade I responded fairly well to the treatment As shown in Table 35 five out of 11 were cured Most of them maintained a normal state for a long time As shown in Table 36 favorable answers were returned to us from the patients who were cured three years ago

As shown in Table 37 we studied 9 cases of rheumatic fever Some of them showed a good response to the treatment in one month but

introduced her to our clinic on account of impairment of the vocal organ. ORL examination failed to detect abnormality other than a hoarse voice when tired.

Clinical findings She developed a clear cut, butterfly shaped rash which was symmetric. She complained of no itching and the symptoms corresponded to the diagnosis given by the dermatologist. To our regret, no detailed renal examination was made except the diagnosis of albuminuria. The pharynx showed a chronic inflammation with slight edema and rash on both sides of the vocal cords. Nasopharyngeal observation indicated abrasion pain and slight post abrasion hemorrhage. The smear preparation revealed a medium inflammatory picture.

Treatment All dermatological medication and treatment was discontinued except application of 1% $ZnCl_2$. For the first few days she complained of severe pain from abrasion and bleeding was observed. On the 5th day of the treatment she reported remission of the redness in her face. Immediately after the treatment facial redness disappeared, but soon returned to its former state. It seemed that the patient told him that the lesion in the face was much improved. (No effect was obtained while she was admitted to the dermatology department.) Since then the treatment was continued every other day and after one and a half months she left the hospital and returned home. Three months later she visited us again and was admitted to the clinic as she had developed rash in the face. The nasopharyngeal treatment had been continued every day. Respondent to the treatment, exfoliation was observed and the redness disappeared gradually. After three months treatment albuminuria turned to negative and complete remission of the rash was attained. In the fourth month she left the clinic. The patient reported no recurrence and after three years she looked younger than before.

Besides this case two other cases of erythema on the face were observed. It is obvious that the nasopharyngeal treatment has significant therapeutic value for the treatment of S.L.E. It is evident from the observation of immediate remission of redness (in one to two seconds after abrasion) and flushing (after 5 to 6 seconds). Because of their apparent antigen-antibody reaction, systemic lupus erythematodes and rheumatism are classified as autoimmune diseases, but there has been no essential treatment discovered for these diseases except natural recovery. In this relation we can explain that natural remission of nasopharyngitis was closely related to natural remission of S.L.E. or rheumatism. It is interesting to note that an artificial process such as nasopharyngeal treatment could have an influence on these diseases.

3) Sclerodermia

Sclerodermia also may be included in the indication. We observed three cases of sclerodermia and obtained softening of the skin after the nasopharyngeal treatment. In one case prolonged stiffness of the hand which is often observed in rheumatic patients, was completely cured. From this observation a relation between sclerodermia and erythema became evident.

4) Nephritis

There has been no essential treatment found for nephritis except natural recovery like those diseases mentioned above. Natural recovery is often observed in acute nephritis. It is therefore necessary to judge the effect of the treatment by means of controlled study. The nasopharyngeal treatment for fragile infants is useful in preventing them from catching cold. In parallel with the recovery albuminuria often disappears. In the following a case report of a 64 year old female with chronic nephritis will be recounted.

Case No. 4 (Fig. 55)

H.I.L. A 64 year old female. Chronic nephritis.

Chief complaint Appearance of albuminuria and hypertension.

History She had been susceptible to common colds in her infancy and used to complain of throat pain, but usually with no abnormal fever. When she was at the age of 59, she was diagnosed as having nephritis after laboratory examination. The prescribed diet was given. Six years ago she was admitted to hospital for systemic examination and again chronic nephritis was diagnosed (albuminuria (+) but RBC (±)). Hemorroids were also detected. For three years since then she had been examined for her albumin status which showed positive. Finally the value of albuminuria reached to (±) and she underwent a tonsillectomy. The result of the operation was excellent and albuminuria was reduced to trace condition. After six months proteinuria increased to positive and about one year ago she visited this clinic. Systemic examination at the time of her visit to our clinic showed blood pressure of 150-110 mmHg and proteinuria was recognized after four drops of sulfosalicylic acid added to the urine. Urinary sedimentation was normal with

a marked inflammation and the local treatment of nasopharyngitis alone lead to a significant recovery from the disease In these instances, nasopharyngitis was laent and because of the lack of subjective symptoms very little medical attention has been directed to it *It is important* to demonstrate the mechanism of the cure process in the course of the nasopharyngeal treatment in the rheumatic patients.

A relationship between the inflammatory focus and autoimmune disease or collagen disease has been suspected by many investigators. In view of the prolonged sensitization concept (OKABAYASHI) a causal relation between them has already been established Clinical observation of nasopharyngitis indicates that the nasopharyngeal treatment has a significant therapeutic value for rheumatism.

The mechanism of cure may be considered from various angles.

1 Removal of the infectious source

2 Secration of steroid (11 OHCS) in blood due to stimulation of the nasopharyngeal mucosa

Application of Nasopharyngeal Treatment for the Purpose of Withdrawal from Corticosteroids

It is considered that the nasopharyngeal treatment is a more useful therapy for rheumatism than steroid treatment From this concept we may facilitate termination of steroid treatment and save the patients from the side effects of corticosteroids by employing this treatment

A steroid derivative 11 OHCS is excreted into the blood upon stimulation of the nasopharynx. The amount of excretion is considered optimum, so that administration of steroids can be discontinued at an early stage of the nasopharyngeal treatment There is no knowing when to discontinue steroid administration, but the author believes it is advisable to stop it at the earliest possible time if no risk is anticipated from the termination I would rather recommend if the nasopharyngeal treatment is safely employed in place of steroid therapy to discontinue the steroid therapy In addition the problem of shock is considered an iatrogenic disease due to administration of steroids. It is reported that serious shock states were caused in patients while operating but the reason for the shock has not been confirmed

The relation between the excretion of 11 OHCS and nasopharyngeal stimulation, as explained above, must be referred However prolonged steroid treatment and the patients with atopic allergic symptoms showed a lowering of 11-OHCS excretion after nasopharyngeal stimulation. Such a reversive phenomenon can be rectified by continuous nasopharyngeal treatment. The author assumes such reversible phenomenon may be related to a shock state.

So far we have discussed clinical observations on rheumatism and nasopharyngitis. Since we think that the presence of nasopharyngitis in a large number of people may play a role in inducing disease like rheumatism of which the pathogenic cause is unknown it is necessary to go further to study the effect of the nasopharyngeal treatment in the patients with diseases like rheumatism.

The following pages will show two or three cases of clinical experiments with nasopharyngeal treatment.

2) Systemic Lupus Erythematodes (SLE)

OKABAYASHI explained that S.L.E. may be induced as a result of prolonged sensitization (1963) We discuss the clinical results obtained by nasopharyngeal treatment for the patients with S L.E. Nasopharyngitis is characteristic *with its chronic inflammatory focus*, and if S L.E. can be cured by the treatment of such inflammation it is quite interesting from the clinical standpoint

Case No 3

C.K. A 50 year old female with S.L.E.

Chief complaint Persistent erythema of the face

History She noticed redness in the face when she felt tired. (July 1964 two years before the first examination at this clinic.) The erythema was present between the eyes and its size was about 2 cm² The shape was irregular The erythema was clearly defined with marked redness. After six months she was diagnosed as having lupus erythematodes but she did not respond to treatment. In November 1965 erythema developed on both her hands and extended to the neck and chest. She visited another university *hospital* and was admitted for two months but no improvement was attained. Around that time she felt pain in the finger joints and rehumatism was diagnosed at the orthopedic department. A dermatologist

the body Tonsillitis and carious teeth are considered to cause focal infection Such causal relationships are often referred to tonsillitis and rheumatism, or tonsillitis and nephritis. Chronic rheumatoid arthritis is often taken up as a target since the onset of pain in joi ts and other portions of the body becomes a guide post for the clinical course. In other words, assuming that tonsillitis is cause of rheumatism, we will stimulate the tonsils and examine whether rheumatic symptoms are aggravated or not or vi ersa. If symptoms of tonsillitis are related to the pathogenic process of rheumatism, tonsillectomy may be indicated. In the case when tonsillitis is determined as an infectious focus, for example in rheumatism, a h gh percentage of cures may be expected following tonsillectomy However it is not always p plicable to rheumatism or nephritis of nknown etiology The concept of focal infection has one weak point that is, a chronic inflammation focus is not always present in these diseases. Therefore tonsillectomy is not alway a useful treatment for rheumatism.

Autoimmunity is a phenomenon discovered in relation to hemolytic anemia in 1946. BURNET completed the theory in 1960 I the development of the theory serum gamma globulin and fluorescei antibody technique ha played an important role. Chronic inflammation focus lso play an important role in the study of toimmune diseases

OKABAYASHI (1963) explained that infection or stimulation from the outside acts directly as heteroimmune but repeated stimulation from outside will be finally transformed to toimmunity This is called *delayed hypersensitivity* Delayed hypersensitivity will occur in the bone marrow spleen and the liver in which reticular cells exist Persistent stimulation is ndispensable in toimmune reactions. A chronic inflammation focus is one of the important origins of stimuli and no other nvolvement of factors are considered.

Collagen disease was named by KLEMPERER to denote the allergic inflammation in the connective tissued. The main ymptoms ar

1 Periarteritis nodosa
2 Rheumatic fever
3 Chronic rheumatoid arthritis
4 Scleroderma
5 Systemic l pus erythematodes
6. Thrombocytopenic purpura

Pathologically it has been characterized as a primary disease causing necrosis and fibrinoid degeneration n the connective tissue. The author postulates that primary infection and secondary nfection would cause allergic changes which stimulate the vasomotor nerve system and change the blood flow to cause various physical alterations. In these diseases the concept of primary infection may be doubtful in rheuma tism at least. Since the etiology is considered a delayed sensitization, collagen diseases cannot be determined as the primary infectious diseases cannot be determined as the primary infectious diseases.

In discussing focal infection autoimmunity and collagen disease a chronic inflammatory focus should be the prime consideration The presence of chronic inflammation may cause allergic damage to various organs in the form of delayed sensitization The postulation is that chronic inflammation as a cause of persistent infection is nothing but nasopharyngitis.

The causal relationship is always observed by pathohistological examination. Clinically we observed that 80% of 4 000 subjects developed more than moderate inflammation in the nasopharynx. Inflammation of the tonsils or gums always accompanies intense nasopharyngeal inflammation, but this is not always associated with those. It is often observed that nasopharyngeal treatment educes remission of the inflammatory symptoms of tonsillitis. This is true also of alveolar pyorrhea. Toothache originating from acute inflammation of the dental root easily responded to nasopharyngeal treatment.

From these bservations we think that the nasopharynx is a site of primary infection and persistent repetition of infection has been observed in this part of the body The inflammation of the nasopharynx has clinical signifi cance since it is a source of infection, utoimmune production or stimulation to cause collagen disease.

There are close relationships among focal infection, autoimmunity collagen disease and nasopharyngitis since they have a common

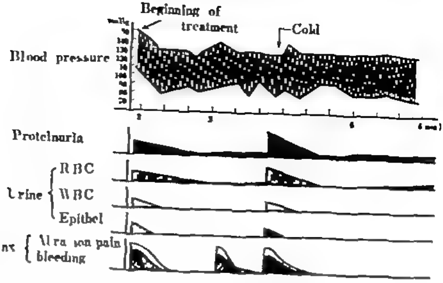

Fig. 55. Case No. 4 H. M 64 Y o M

four to five RBC and the same amount of WBC and epithelial cells. However nasopharyngeal observation revealed presence of an intense inflammation and a post abrasive hemorrhage with a severe abrasion pain.

Clinical course Daily nasopharyngeal treatment *with 1 ZnCl₂ had been exercised* and the clinical course was observed At first she complained of abrasion pain, but it gradually decreased and in two weeks almost no abrasion pain was present. During that period blood pressure dropped from 140–130 to 90–80 mmHg and proteinuria could be recognized only with six drops of sulfosalycylic acid. RBC count was two to three and in three weeks after the treatment it disappeared. After two months she caught cold and discontinued treatment for one week. The reexamination disclosed that proteinuria increased to react to two drops of sulfosalycylic acid and a large number of RBC WBC and epithelial cells appeared. The nasopharyngeal observation indicated the presence of intense inflammation with a severe abrasion pain and bleeding The smear preparation also showed the existence of marked inflammation. The treatment had been continued for 20 days and her nasopharyngeal condition and albuminuria improved. She left the clinic to travel abroad. After one year of overseas life she was examined for blood pressure and proteinuria and was quite healthy (Fig 55)

As observed in the above case improvement of albuminuria did not indicate excellent therapeutic response but the worsening of nasopharyngitis ran in parallel with deterioration of albuminuria and this phenomenon was quite interesting The author wishes to obtain more cases like this to study in detail by means of biopsy

However in infants, as mentioned in the foregoing pages, we observed good results in feeble children who habitually caught cold and produced proteinuria It seems interesting to observe the clinical effects of the nasopharyngeal treatment in patients with impaired liver or thyroid gland. The author has not experienced sufficient cases of this category but once observed lowered GOT and GPT after the treatment of nasopharyngitis. Another case was related to reduced basic metabolism due to throidal disorder The treatment successfully achieved normal function of the thyroid gland. In an elevated metabolism case this treatment reduced the function to the normal state It is a desire of the author that readers will further investigate such relations.

Diabetes mellitus is also an interesting theme of the nasopharyngeal treatment The pathogenic mechanism of diabetes is still in question but some clinicians think that impairment of the pancreas in the diabetic may be related to autoimmune diseases and from this standpoint we might find some clinical clues in the treatment of diabetes.

5) Nasopharyngitis as an Infectious Source

The term focal infection was first used by Frank Billings in his report carried in JAMA in 1938 to explain the onset of infection by intrusion of bacteria persisting in so...

the body. Tonsilitis and carious teeth are considered to cause focal infection. Such causal relationships are often referred to tonsillitis and rheumatism, or tonsillitis and nephritis. Chronic rheumatoid arthritis is often taken up as a target since the onset of pain in joints and other portions of the body becomes a guide-post for the clinical course. In other words, assuming that tonsilitis is cause of rheumatism, we will stimulate the tonsils and examine whether rheumatic symptoms are aggravated or not or visa versa. If symptoms of tonsillitis are related to the pathogenic process of rheumatism, tonsillectomy may be indicated. In the case when tonsilitis is determined as an infectious focus, for example in rheumatism, high percentage of cures may be expected following tonsillectomy. However it is not always applicable to rheumatism or nephritis of unknown etiology. The concept of "focal infection" has one weak point, that is, a chronic inflammation focus is not always present in these diseases. *Therefore tonsillectomy is not always a useful* treatment for rheumatism.

Autoimmunity is phenomenon discovered in relation to hemolytic anemia in 1946. BURNET completed the theory in 1960. In the development of the theory serum gamma globulin and fluorescein antibody technique has played an important role. Chronic inflammation focus also plays an important role in the study of autoimmune diseases.

OKABAYASHI (1963) explained that infection or stimulation from the outside acts directly as heteroimmune, but repeated stimulation from outside will be finally transformed to autoimmunity. This is called "*delayed hypersensitivity*". Delayed hypersensitivity will occur in the bone marrow, spleen and the liver in which reticular cells exist. Persistent stimulation is indispensable in autoimmune reactions. A chronic inflammation focus is one of the important origins of stimuli and no other involvement of factors are considered.

Collagen disease was named by KLEMPERER to denote the allergic inflammation in the connective tissued. The main symptoms are

1. Periarteritis nodosa
2. Rheumatic fever
3. Chronic rheumatoid arthritis
4. Scleroderma
5. Systemic lupus erythematodes
6. Thrombocytopenic purpura

Pathologically it has been characterized as a primary disease causing necrosis and fibrinoid degeneration in the connective tissue. The author postulates that primary infection and secondary infection would cause allergic changes which stimulate the vasomotor nerve system and *change the blood flow to cause* various physical alterations. In these diseases the concept of primary infection may be doubtful in rheumatism at least. Since the etiology is considered a delayed sensitization, collagen diseases cannot be determined as the primary infectious diseases cannot be determined as the primary infectious diseases.

In discussing focal infection, autoimmunity and collagen disease, a chronic inflammatory focus should be the prime consideration. The presence of chronic inflammation may cause allergic damage to various organs in the form of *delayed sensitization. The postulation is that* chronic inflammation as a cause of persistent infection is nothing but nasopharyngitis.

The causal relationship is always observed by pathohistological examination. Clinically we observed that 80% of 4 000 subjects developed more than moderate inflammation in the nasopharynx. Inflammation of the tonsils or gums always accompanies intense nasopharyngeal inflammation but this is not always associated with those. It is often observed that nasopharyngeal *treatment induces remission of the* inflammatory symptoms of tonsillitis. This is true also of alveolar pyorrhea. Toothache originating from acute inflammation of the dental root easily responded to nasopharyngeal *treatment.*

From these observations we think that the nasopharynx is site of primary infection and persistent repetition *of infection has been ob*served in this part of the body. The *inflammation of the nasopharynx* has clinical significance since it is source of infection, autoimmune production or stimulation to cause collagen disease.

There are close relationships among focal infection, autoimmunity collagen disease and nasopharyngitis since *they* have a common

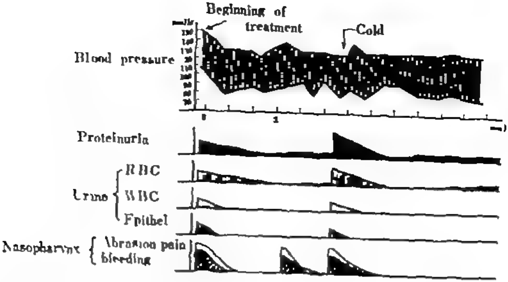

Fig. 55. Case No. 4 H M 64 Y o, M

four to five RBC and the same amount of WBC and epithelial cells. However nasopharyngeal observation revealed presence of an intense inflammation and a post abrasive hemorrhage with a severe abrasion pain.

Clinical course Daily nasopharyngeal treatment with 1 % $ZnCl_2$ had been exercised and the clinical course was observed. At first she complained of abrasion pain, but it gradually decreased and in two weeks almost no abrasion pain was present. During that period blood pressure dropped from 140–130 to 90–80 mmHg and proteinuria could be recognized only with six drops of sulfosalycylic acid. RBC count was two to three and in three weeks after the treatment it disappeared After two months she caught cold and discontinued treatment for one week. The reexamination disclosed that proteinuria increased to react to two drops of sulfosalycylic acid and a large number of RBC WBC and epithelial cells appeared The nasopharyngeal observation indicated the presence of intense inflammation with a severe abrasion pain and bleeding The smear preparation also showed the existence of marked inflammation. The treatment had been continued for 20 days and her nasopharyngeal condition and albuminuria improved. She left the clinic to travel abroad. After one year of overseas life she was examined for blood pressure and proteinuria, and was quite healthy (Fig 55)

As observed in the above case improvement of albuminuria did not indicate excellent therapeutic response but the worsening of nasopharyngitis ran in parallel with deterioration of albuminuria and this phenomenon was quite interesting The author wishes to obtain more cases like this to study in detail by means of biopsy

However in infants, as mentioned in the foregoing pages, we observed good results in feeble children who habitually caught cold and produced proteinuria. It seems interesting to observe the clinical effects of the nasopharyngeal treatment in patients with impaired liver or thyroid gland The author has not experienced sufficient cases of this category but once observed lowered GOT and GPT after the treatment of nasopharyngitis. Another case was related to reduced basic metabolism due to throidal disorder The treatment successfully achieved normal function of the thyroid gland. In an elevated metabolism case this treatment reduced the function to the normal state It is a desire of the author that readers will further investigate such relations.

Diabetes mellitus is also an interesting theme of the nasopharyngeal treatment The pathogenic mechanism of diabetes is still in question but some clinicians think that impairment of the pancreas in the diabetic may be related to autoimmune diseases and from this standpoint we might find some clinical clues in the treatment of diabetes.

5) Nasopharyngitis as an Infectious Source

The term focal infection was first used by Frank Billings in his report carried in JAMA in 1938 to explain the onset of infection by intrusion of bacteria persisting in some part of

the body Tonsilitis and carious teeth are considered to cause "focal infection" Such causal relationships are often referred to tonsillitis and rheumatism, or tonsillitis and nephritis. Chronic rheumatoid arthritis is often taken up as a target since the onset of pain in joints and other portions of the body becomes guide-post for the clinical course. In other words, assuming that tonsillitis is a cause of rheumatism, we will stimulate the tonsils and examine whether rheumatic symptoms are aggravated or not or vice versa. If symptoms of tonsillitis are related to the pathogenic process of rheumatism, tonsillectomy may be indicated. In the case when tonsillitis is determined as an infectious focus, for example in rheumatism, a high percentage of cures may be expected following tonsillectory However it is not always applicable to rheumatism or nephritis of unknown etiology The concept of focal infection" has one weak opint, that is, a chronic inflammation foucs is not alw y present in these diseases. Therefore tonsillectomy is not alw ys a useful treatment for rheumatism.

Autoimmunity is a phenomenon discovered in relation to hemolytic anemia in 1946. BURNET completed the theory in 1960 In the development of the theory serum gamma globulin and fluorescein antibody technique has played an important role. Chronic inflammation focus also plays an important role in the study of autoimmune diseases.

OKABAYASHI (1963) explained that infection or stimulation from the outside acts directly as heteroimmune but repeated stimulation from outside will be finally transformed to utoimmunity This is called *delayed hypersensitivity* Delayed hypersensitivity w'll occur in the bone marrow spleen and the liver in which reticular cells exist. Persistent stimulation is indispensable in autoimmune reactions. A chronic inflammation focus is one of the important origins of stimuli and no other invol ment of factors are considered.

Collagen disease was named by KLEMPERER to denote the allergic inflammation in the connective tissued. The main symptoms are

1 Periarteritis nodosa
2. Rheumatic fever
3. Chronic rheumatoid arthritus
4 Sclerodermia
5 Systemic lupus erythematodes
6. Thrombocytopenic purpura

Pathologically it has been characterized as a primary disease causing necrosis and fibrinoid degeneration in the connective tissue. The a thor postulates that primary infection and secondary infection would cause allergic changes which stimulate the vasomotor nerve system and change the blood flow to cause various physical alterations. In these diseases the concept of primary infection may be doubtful in rheumatism at least. Since the etiology is considered a delayed sensitization, collagen diseases cannot be determined as the primary infectious diseases cannot be determined as the primary infectious diseases.

In discussing focal infection, utoimmunity and collagen disease, a chronic inflammatory focus should be the prime consideration. The presence of chronic inflammation may cause allergic damage to various organs in the form of delayed sensitization. The postulation is that chroni inflammation as cause of persistent infection is nothing but nasopharyngitis.

The causal relationship is always observed by pathohistological examination. Clinically we observed that 80 of 4 000 subjects developed more than moderate inflammation in the nasopharynx. Inflammation of the tonsils or gums always accompanies intense nasopharyngeal inflammation, but this is not always associated w th those It is often observed that nasopharyngeal treatment induces remission of the inflammatory symptoms of tonsillitis. This is true also of alveolar pyorrhea. Toothache originating from acute inflammation of the dental root easily responded to nasopharyngeal treatment.

From these observations we think that the nasopharynx is a site of primary infection and persistent repetition of infection has been observed in this part of the body The inflammation of the nasopharynx has clinical significance since it is a source of infection, autoimmune production or stimulation to cause collagen disease.

There are close relationships among focal infection, autoimmunity collagen disease and nasopharyngitis since they have a common

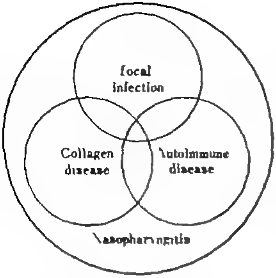

Fig 56.

etiological basis. From the point of the focal infection assumption of the infection site is important so the existence of antibodies is the primary problem in autoimmunity (Fig 56)

Examination of inflammatory foci closely related to nasopharyngitis indicated that infection or antibody reaction are not the primary objects of the study of the pathogenic process of collagen disease since they do not represent histopathological aspects of collagen diseases.

The pathogenic process of nasopharyngitis demonstrates close relationships to secondary infections. Some clinicians are trying to investigate relations between nasopharyngeal treatment and clinical courses of allergic diseases.

So far as his consideration concerns, the author would like to introduce to these secondary inflammations (focal infection, autoimmune disease or collagene disease) the thought of "**Inflammation Without Infection** which is controled remotely from the other infectious part (like nasopharyngitis) (Of course these inflammation without infection may sometimes have the second infection of bacilli such as nephritis)

2. Significance of Nasopharyngitis in Infectious and Allergic Diseases of Unknown Origin

1) Habitual Aphthosis

Habitual aphthosis has been thought to occur in vitamin deficiency in gastrointestinal disorders, common cold or after drinking, but there is no conclusive evidence. The author examined the nasopharynx of the patients and the observed presence of intense inflammation in their nasopharyngeal cavity. The treatment of the nasopharyngeal cavity reduced the inflammation.

Case No. 5

Y.Ja. 32 year old male. Habitual aphthosis.

Chief complaint: Pain in the mouth. He suffered from hooping cough at age of six. Since then he often caught cold. Aphthosis appeared frequently at age of 7–8. Its duration used to be 10–14 days. Various efforts were in vain.

Clinical findings: Aphtha of 3 mm in size appeared on the left buccal mucosa and there were 2 aphthas on the lower gums with severe pain. Abrasion of the nasopharynx produced pain and bleeding. The pain persisted for 5 hours. The smear sample from the nasopharynx indicated desquamation of ciliated epithelial cells and presence of wandering leucocytes and proliferation of bacteria. The presence of erosion at the nasopharynx was also demonstrated.

Clinical course: All medications were discontinued except the nasopharyngeal treatment with 1% $ZnCl_2$ (with small amount of anesthetic added). The treatment was carried out once daily. The first treatment reduced the pain and white ulcers diminished in 4–5 days. Prolonged treatment inhibited aphthosis and the ulcers became typical. The patient has never experienced aphthosis since his complete recovery.

Habitual aphthosis is difficult to cure completely. It sometimes stops producing any symptoms for unknown reasons. In the past we reported 19 cases of aphthosis treated by means of nasopharyngeal treatment.

Table 38 shows the degrees of nasopharyngitis and the frequency of aphthous. It indicates that in habitual cases accompanied with severe inflammation and abrasion pain, nasopharyngitis was intense. In slight aphthosis, nasopharyngitis was also mild. Table 39 illustrates the relation between the number of lesions of aphthosis and the severity of nasopharyngitis. Table 40 shows the clinical value of the nasopharyngeal treatment in reducing frequency of aphthosis. Assessment of effectiveness is given to cases which had been free from the recurrence of aphthosis over six months of observation. It is generally observed that the nasopharyngeal treatment will improve symptoms, but in some cases periodical recurrence

Table 38 Severity of nasopharyngitis and frequency of aphthosis.

no effect	1	0	4	3

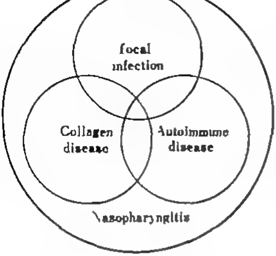

Fig. 56.

etiological basis. From the point of the focal infection assumption of the infection site is important, so the existence of antibodies is the primary problem in autoimmunity (Fig 56)

Examination of inflammatory foci closely related to nasopharyngitis indicated that infection or antibody reaction are not the primary objects of the study of the pathogenic process of collagen disease since they do not represent histopathological aspects of collagen diseases.

The pathogenic process of nasopharyngitis demonstrates close relationships to secondary infections. Some clinicians are trying to investigate *relations between nasopharyngeal* treatment and clinical courses of allergic diseases.

So far as his consideration concerns, the author would like to introduce to these secondary *inflammations (focal infection autoimmune* disease or collagene disease) the thought of **Inflammation Without Infection**" which is controled remotely from the other infectious part (like nasopharyngitis) (Of course these inflammation without infection may sometimes have the second infection of bacilli such as "nephritis")

10th day the abrasion pain was reduced and at the same time the headache was alleviated. Radiation of the pain to the teeth also decreased. After 30 days the abrasion pain and bleeding were completely healed. After two months marked improvement was observed and in 6 months complete cure was recorded.

Ten cases of primary alveolar pyorrhea (bleeding from gums) were treated with the nasopharyngeal treatment, the results of which are shown in Table 41. Table 41 shows the clinical value of local treatment in the cases of alveolar pyorrhea. Assessment of the efficacy of the treatment was made by comparing the amount of bleeding before and after the treatment (Fig. 57).

4) Gastric Ulcer

As discussed in the previous pages, gastric ulcer was treated by nasopharyngeal treatment and good results were obtained. The following is a case report.

Case No. 7

S.S. A 49 year old male. Gastric ulcer and diabetes mellitus.

Chief complaint. Gastric ulceration and dryness of the mouth.

History. Gastric ulcer was diagnosed 10 years previously and several examinations had been carried out with the same results. Gastroscopy showed an ulcer. Diet and medication failed to improve it. Recent gastroscopy showed a 1.5cm ulcer in the gastric mucosa. The patient also developed diabetes mellitus.

Clinical course. All medications were discontinued except nasopharyngeal treatment with 1% $ZnCl_2$. Intense abrasion pain and bleeding were observed. On the 5th day the pain and bleeding decreased and in 10 days, NP indicated disappearance of the niche with no epigastric pain and occult blood. Gastroscopy showed normal gastric mucosa and after two years no abnormality was found in gastroscopy. Diabetes mellitus was also healed, but this case will be discussed later in another part of this report. A total of 5 cases of gastric ulcer were shown to be recovered in NP and gastroscopy. In duodenal cases similar results were observed. Relapse was rare if sufficient treatment was given.

The above cases were relatively mild ones and we cannot conclude that nasopharyngeal treatment would be effective in cases requiring surgical operation, but we consider it effective in post operation ulcers.

5) Other Chronic Inflammations

In the foregoing pages we have referred to the effectiveness of treatment in rheumatism and phthisis of so-called non-suppurative inflammation.

The concept of focal infection, autoimmunity and collagen disease is directly related to the pathogenic process of nasopharyngitis and secondary infection is considered to be induced by the presence of a chronic inflammatory focus. This will be explained in the case of chronic habitual parotitis in children.

Case No. 8

R.H. 10 year old girl. Chronic parotitis.

Chief complaint. Relapsing parotitis.

History. Swelling and pain were felt in the left parotid gland. After a cold, excretion of pus from the left side cheek was detected. Occasional swelling of the parotid was repeated. Pediatrists and otorhinologists prescribed antibi-

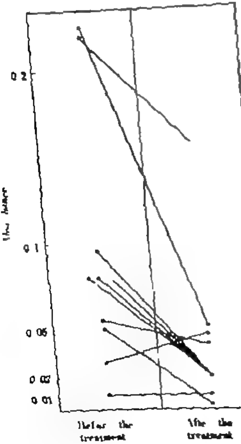

Fig. 57. Comparison in amount of bleeding before and after the nasopharyngeal treatment

was noted. Continuous treatment reduced the frequency of aphthous to zero despite the deterioration of nasopharyngitis. Clinical phenomena such as this case can be observed in other diseases. Complete non recurrence state for the observation period is assessed as complete cure. In this table at least 7 cases out of 19 were cured completely and this result is interesting since the nasopharyngeal treatment is as useful as the steroid treatment.

Pathologically aphthous is a minor ulceration of the oral mucosa and no etiology has been established but this disease has the following characteristics.

1 The appearance of ulcers is related to the progress of nasopharyngitis.

2 Ulceration of aphthous is considered to be of non bacterial origin or to be an inflammation due to secondary infection.

Gastric ulcer or duodenal ulcer may be included in this category and the nasopharyngeal treatment has been observed useful for the treatment of diseases of this category. Gastric ulcer or duodenal ulcer are considered due to autonomic nerve disorders. Consideration on these diseases will be made in a later chapter

2) Behçet's Disease

We have studied two cases of Behçet's disease. One case had marked improvement in 10 days after the start of the nasopharyngeal treatment and the clouded aqueous humor recovered its clarity but the patient did not come to our clinic any more. Another case was a confirmed case of Behçet's disease as diagnosed by an oculist. However no ocular symptoms appeared at time of the patient's visit to this clinic, except persistent aphthous. Aphthous was cured by the treatment of nasopharyngitis.

Behçet's disease although it is a relative to aphthous, causes severe ocular impairment and the symptoms are more intense than aphthous.

To our regret we have seen only two cases of Behçet's disease, but one case responded excellently to the nasopharyngeal treatment and aphthous was cured completely. Group trials for Behçet's disease are being prepared, and we expect good clinical results from the nasopharyngeal treatment.

3) Alveolar Pyorrhea

Case No. 6

S. K. A 36 year old male. Alveolar pyorrhea.

Chief complaint Headache dizziness, but alveolar pyorrhea was not the chief complaint.

History Severe headache had been experienced for several years with occasional dizziness. Alveolar pyorrhea was observed on the mandible and three incisors needed extraction.

Clinical course Nasopharyngitis had not been detected but the abrasion preparation indicated the presence of intense inflammation of the pharynx. Application of 1 $ZnCl_2$ with local anaesthetics to the nasopharynx produced bleeding which continued for 4 hours. During the nasopharyngeal treatment pain radiated towards the maxilla and mandible and the patient felt as if the root had been lifted. A similar sensation was felt the next day after the treatment. After the 5th day of treatment he noticed pyorrhea begin to decrease On the

Table 41 Cases of gingival bleeding and gingival pain.

Case No.	Age	Sex	Main symptoms	Nasopharynx Abrasion	Nasopharynx Bleeding	Picture of epithelium smear preparations (inflammation)	Duration of treatment	Effectiveness
1	38	ʏ	Gingival bleeding, gingival pain	++	++	intense	1 month	dramatic
	25	ʏ	Gingival bleeding	++		—	1 month	effective
3	23	♂	Gingival bleeding gingival pain	+++	++	intense	1 month	dramatic
4	[illegible]5	♂	Gingival bleeding	++	—	moderate	1 month	no effect
5	19	♂	Gingival pain		+	—	1 month	dramatic
6	29	ʏ	Gingival pain	++	+	moderate	1 month	effective
7	39	ʏ	Gingival bleeding	+	++	moderate	1 month	effective
8	16	♀	Gingival pain	++	+	moderate	1 month	no effect
9	26	♀	Gingival bleeding	+	++	moderate	1 month	dramatic
10	32	♀	Gingival bleeding	++	++	moderate	1 month	no effect

10th day the abrasion pain was reduced and at the same time the headache was alleviated. Radiation of the pain to the teeth also decreased. After 20 days the abrasion pain and bleeding were completely healed. After two months marked improvement was observed and in 6 months complete cure was recorded.

Ten cases of primary alveolar pyorrhea (bleeding from gums) were treated with the nasopharyngeal treatment, the results of which are shown in Table 41. Table 41 shows the clinical value of local treatment in the cases of alveolar pyorrhea. Assessment of the efficacy of the treatment was made by comparing the amount of bleeding before and after the treatment (Fig. 37).

4) Gastric Ulcer

As discussed in the previous pages, gastric ulcer was treated by nasopharyngeal treatment and good results were obtained. The following is a case report.

Case No. 7

S.S. A 49 year old male. Gastric ulcer and diabetes mellitus.

Chief complaint Gastric ulceration and dryness of the mouth.

History: Gastric ulcer was diagnosed 10 years previously and several examinations had been carried out with the same results. Gastroscopy showed an ulcer. Diet and medication failed to improve it. Recent gastroscopy showed a 1.5cm ulcer in the gastric mucosa. The patient also developed diabetes mellitus.

Clinical course All medications were discontinued except nasopharyngeal treatment with 1% $ZnCl_2$. Intense abrasion pain and bleeding were observed. On the 5th day the pain and bleeding decreased and in 10 days, XP indicated disappearance of the niche with no epigastric pain and occult blood. Gastroscopy showed normal gastric mucosa and after two years no abnormality was found in gastroscopy. Diabetes mellitus was also healed, but this case will be discussed later in another part of this report. A total of 5 cases of gastric ulcer were shown to be recovered in XP and gastroscopy. In duodenal cases similar results were observed. Relapse was rare if sufficient treatment was given.

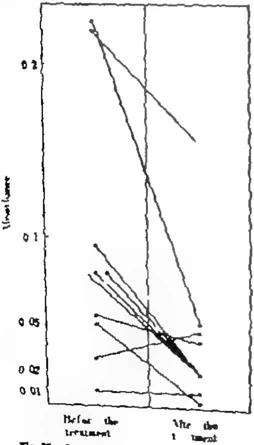

Fig. 37 Comparison in amount of bleeding before and after the nasopharyngeal treatment

The above cases were relatively mild ones and we cannot conclude that nasopharyngeal treatment would be effective in cases requiring surgical operation, but we consider it effective in post operative ulcers.

5) Other Chronic Inflammations

In the foregoing pages we have referred to the effectiveness of treatment in rheumatism and aphthous of so-called non-suppurative inflammation.

The concept of focal infection, autoimmunity and collagen disease is directly related to the pathogenic process of nasopharyngitis and secondary infection is considered to be induced by the presence of a chronic inflammatory focus. This will be explained in the case of chronic habitual parotitis in children.

Case No. 8

R.H. 10 year old girl. Chronic parotitis.

Chief complaint Relapsing parotitis

History Swelling and a pain were felt in the left parotid gland. After a cold, excretion of pus from the left side cheek was detected. Occasional swelling of the parotid was repeated. Pediatrics and otorhinologists prescribed various

antibiotics but the patient failed to improve. When she visited our clinic, excretion of pus under pressure from the left parotid gland was observed No salivary calculus was found in XP but intense inflammation in the duct was observed. A number of staphylococci aureus were discovered in the pus. Nasopharyngeal examination produced abrasion pain and bleeding The smear preparation showed the presence of intense inflammation

Clinical course All other medications were stopped except the nasopharyngeal administration of 1% $ZnCl_2$. The abrasion pain and bleeding continued for about one month From the start of the treatment the swelling began to decrease and excretion of pus had almost disappeared on the 5th day of the treatment The patient was treated for another 6 months and a slight relapse was noted after 2 months of treatment, but continuous therapy inhibited the recurrence of the symptoms.

We experienced three other cases of *parotitis* which took a similar clinical course. In this chapter attention was paid to the fact that the chronic inflammation focus existed and excreted a large number of infectious microorganisms. In these chronic inflammatory diseases we often found that nasopharyngeal *treatment* achieved successful results in cases like chronic otitis media, chronic rhinitis chronic pharyngitis and chronic nasopharyngitis. It also produced excellent results in acute cases of these chronic inflammatory diseases but when they were in the silent state, the treatment was less effective or took much time to alleviate the symptoms, as in the case of chronic sinusitis. It is interesting to see that it is clinically effective in the treatment of inflammation originating from injection of microorganisms.

6) Allergy

Allergic rhinitis is one of the commonest disease of otorhinolaryngology Pirquet first reported antigen antibody reaction as a cause of allergy and some investigators, such as Hansel include allergic rhinitis among the typical allergic cases because of the positive intracutaneous reaction and provacative reaction of nasal mucosa and marked increase of eosinophilic leucocytes in nasal fluid and in the blood

The author observed a number of cases showed negative intracutaneous reaction despite repeated recurrence of allergic nasal symptoms. In some cases eosinophilia was noted while in others it was not. Hyposensitization therapy is considered useful since reagin and blocking antibody are observed in the patients. However the author postulates that reagin or blocking antibody production is nothing but a biological phenomenon and hyposensitization therapy cannot attain a complete cure. The fundamental rationale is that the author places importance on the presence of nasopharyngitis in allergic rhinitis. The observation of clinical conditions disclosed that the patients first had an unusual feeling at the soft palate and sniffling followed The unusual feeling at the soft palate indicates the existence of abnormal conditions. Some patients told us they had a cold and recurrence of the cold symptoms formed a habituation From the clinical findings as such it is reasonable to consider the relationship between nasopharyngitis and allergic rhinitis. We examined nasopharyngeal conditions in randomly selected patients, and the results are shown in Table 42 As shown we confirmed the existence of an intense inflammation or erosion in the nasopharynx. Encouraged by these findings, we carried out the local treatment of the nasal abrasion with 1% $ZnCl_2$ solution and recorded the results.

Case No. 9 (Figs. 58, 59)

K.T A 25 year old male Allergic rhinitis.

History The patient had been suffering from chronic allergic rhinitis for three years mostly

in winter but occasionally in summer. Nasal obstruction and rhinorrhea fluid had been persistent and pallid swelling of the nasal mucosa was observed. Laboratory data indicated 80% presence of eosinophil leucocytes in the nasal fluid and 700 pcs. in the blood. A severe postabrasion hemorrhage and marked exfoliation of ciliated epithelium, appearance of wandering leucocytes and proliferation of staphylococci aureus were noted.

Clinical course. According to the patient, antihistamine and other anti-allergic preparations had no effect. The usual nasopharyngeal treatment alone was prescribed and other treatment was discontinued. No bleeding was observed on the 10th day of the treatment and abrasion pain disappeared on the 14th day. Continuous treatment obtained growth of epithelial cells and on the 60th day the growth of normal ciliated epithelia was observed. Allergic symptoms had almost disappeared on the 35th day. On the 100th day eosinophils, as shown in Figs. 58, 59, disappeared, and all symptoms also disappeared.

Table 43 shows the clinical results of the nasopharyngeal abrasion in allergic cases. As shown in Table 44, 6 cases were completely cured, 9 cases improved and 4 cases were unchanged. The complete cure meant recovery of normal values of eosinophil leucocytes in nasal fluid and blood. Alleviation signifies that the clinical symptoms were reduced enough in severity to allow the patients to return to work and recovery of eosinophil leucocyte values to the normal standards. An interesting clinical observation, that is a marked imporvement of asthma, urticaria, atopic dermatitis and food allergy, was made, and from these results the local abrasion treatment is not only useful in allergic rhinitis but also in other diseases complicated by allergy.

Gamma Globulin Alteration

Clinical usefulness of nasopharyngeal abrasion in the treatment of allergic rhinitis and other allergic symptoms, and normalization of eosinophil leucocyte values were described in the preceeding pages. As mentioned already, clinical patterns of allergic symptom are not always accompanied by antigen-antibody reactions, but

only by eosinophilia. In general the cases with antigen antibody *reaction are called nasal allergy* and others are called vasomotor rhinitis to *distinguish between them. However* if we place importance on the clinical findings we should reconsider the significance of antigen antibody reaction in allergic rhinitis. We have studied how the nasopharyngeal treatment affects antigen antibody reaction. The clinical experiments were carried out to examine the alteration of immune globulin in two groups of patients, one group was exclusively treated with nasopharyngeal abrasion and the other with hyposensitization. *The* experiments were carreid out by Takayama of our department. Twenty eight patients who showed positive *antigen* antibody reaction were devided into two groups of 14 each. Group A was treated with hyposensitization and *gorup B exclusively with the* nasopharyngeal treatment.

Tables 45 and 46 illustrate the results.

Table 45 represents the results of group A and Table 46 group B. Both groups were treated for 3 months. With the exception of 3 cases, group A showed 11 effective cases including 3 excel*lent and group B showed 12 effective and 2 non* effective cases. A comparison of IgA and IgG before the treatment disclosed that no IgG changes were observed in *either gorup* and the general picture showed no definite direction. In contrast changes of IgA showed an increase after the treatment and no reduction was observed either group. As shown in the table in *7 cases of group* A IgG increased after the treatment while group B and 9 cases (64) of elevation.

Clinical Significance of Nasopharyngeal Treatment in Treating Nasal Allergy

We have described how the nasopharyngeal treatment was not only useful in treating nasal allergy but also produced changes in the serum immunoglobulin values. *It is a well-known fact* that a certain type *of allergy reacts sharply to* specific antigen and provokes allergic symptoms. *However we cannot* say that allergy is equal to antigen-antibody reaction for the following reasons.

1 We observe some cases lacking antigen antibody raection or eosinophilia despite their *typical allergic onset.*

Table 45 Group treated by hyposensitization.

2. Antibody antigen reaction is explained as a biological reaction of protein or some complex particle, but we can observe that a simple stimulant (for example SO_2) or physical changes such as coldness may provoke allergic symptoms

3 If a biological reaction is considered as an antigen antibody reaction we cannot explain the occurrence of double reaction to different antigens.

4 Hyposensitization therapy is a treatment of allergy by repeated injection of antigen but it increases reagin. Blocking antibody is confirmed but it must be a treatment to make the body accustomed to a stimulant.

5 The usefulness of the non specific therapy or the treatment of anti-chemical mediator may suggest an involvement of factors other than antigen-antibody reaction.

6 Nasopharyngeal treatment is applicable to any allergic symptoms and normalizes eosinophil leucocyte values. It also influences serum immune globulin in the same manner as the hyposensitization treatment.

From the above observations we may conclude that an antigen-antibody reaction may cause allergic symptoms, but it is not the exclusive reason. As explained previously the nasopharyngeal treatment attained good results in nasal allergy responding to the alleviation of nasopharyngitis. From this fact nasal allergy is related to nasopharyngitis in a wider sense than antigen antibody reaction.

Further investigation of the relation between nasopharyngitis and functional disorders of the nasopharynx is explained in Table 48 which includes the cases collected by TAKAYAMA The table contains groups C and D in addition to B Group B consisted of 14 typical allergic cases with intracutaneous reaction, eosinophilia and positive clinical symptoms. Group C consisted of negative intracutaneous reaction, but with clinically positive symptoms and gorup D was all negative except for clinical symptoms (snuffling and nasal congestion) These 33 cases were treated exclusively by the nasopharyngeal therapy (1 / $ZnCl_2$) and the results were good in all groups. Besides these groups, hypertrophic rhinitis responded well to the treatment. Conchotomy has been used in a rhinitis chronica hypertrophica vasomotorica but persistent relapse is a threat. It often complicates nasopharyngitis but local treatment alone produces good results. Some patients often mistake nasopharyngeal abnormality as a stuffy nose. Since the disorder is not of a physical nature clinical observation discloses normal findings and some clinicians might conclude that the patient had nasal neuritis. However abrasion treatment might satisfy the patient. The sensation of nasopharyngeal disorders should appear on the dorsal portion of the soft palate, but it often radiates to the nasopharynx and makes the patient complain of nasopharyngeal abnormality or nasopharyngeal neurosis. Various types of nasal allergy (including the so-called vasomotor rhinitis) and habitual hypertrophy of the nasal mucosa usually complicates nasopharyngitis and local treatment often alleviates the allergic symptoms. From this observation we may find a causual relationship in nasopharyngitis and the functional disorders of the nose

Effect of the Nasopharyngeal Therapy in Other Allergic Diseases

From the clinical observation of allergic rhinitis we often observe complication of the

llergic diseases. Bronchial asthma, urticaria and atopic dermatitis are often observed complicated with nasal allergy. We frequently observed alleviation of these complicate allergic symptoms in association with the improvement of allergic rhinitis. Clinical cases representing each complication are described as follows.

Asthma

Patients with acute or chronic bronchial asthma often have the complication of a nasopharyngeal inflammation. We carried out clinical experiments in asthmatic patients and observed the results. 14 cases were completley cured. Two cases are described below.

Case No. 10

A 72 year old male, with bronchial asthma.

History: H had suffered from pediatric asthma at the age of 4, and it lasted till the present as chronic asthma. When the attack was severe, he had to be hospitalized for 2-3 weeks. Attacks had occurred once or twice a year but no seasonal occurrence was noted. After various tests he was found slightly sensitive to home dust, but no specific antigen was detected. Hyposensitization of home dust was tried but gave no results. Various treatments failed to produce good results. He had been prescribed steroid since 5 years previously on a constant basis. He used to increase the dose at the onset of the symptoms.

Clinical course: He visited our clinic a year ago. A slight bleeding and moderate pain were noted at the abrasion test. The smear specimen disclosed the presence of an intense inflammation. 11-OHCS showed a decrease after the local treatment. The continuous local treatment with 1% $ZnCl_2$ inhibited the symptoms entirely. (The patient always had cough in spite of the steroid treatment.) The steroid was tentatively reduced to one-half and the patient experienced intense coughing. The steroid was increased to the previous level. It was used in combination with nasopharyngeal treatment for 3 months. It was completely terminated after 6 months. The nasopharyngeal treatment is still continuing and no recurrence is observed.

11-OHCS shows an increase of 20% after the treatment.

Case No. 11

A six year old boy with asthma.

Chief complaint: Stridor.

History: He often used to catch cold with cough in his early infanthood and it was diagnosed by a pediatrist as bronchitis. Three years ago the onset of coughing became severe and frequent and he was admitted to a hospital. After two weeks of steroid therapy the symptoms were improved and he left the hospital. After discharge, the symptoms returned and predonin was prescribed. He visited our clinic on the recommendation of the pediatric department of the university hospital.

Clinical course: All medications were discontinued. (Steroids were to be permitted only when the symptoms were severe, but they were not used.)

The nasopharyngeal treatment with 1% $ZnCl_2$ was employed exclusively. A marked bleeding was observed at the abrasion test and the boy cried because of severe pain.

By the 10th day no bleeding was observed and the abrasion pain disappeared on the 14th day. Coughing was reduced in both frequency and severity after the treatment. The symptoms disappeared in half a month. After two months slight cough was observed 3 times, but after 5 months no recurrence was recorded and he was discharged from the clinic.

After six months he again visited our clinic but the treatment of nasopharyngeal abrasion cured the disease in one week. No recurrence has been reported in the past of months.

The above two cases were confirmed to be bronchial asthma after an intensive laboratory examination by specialists. Steroids were prescribed in both cases but failed to cure the chronic symptoms. It seems to us that the nasopharyngeal treatment made it possible to terminate the persistent symptoms.

Nasopharyngeal Treatment for Other Allergic Diseases

The effects of nasopharyngeal treatment for various allergic diseases were assessed in the previous pages. A food allergy which persisted for a long time was cured by the local treatment. In the following cases of urticaria, atopic dermatitis was diagnosed. The author believes that these diseases are directly relatied to nasopharyngitis and the improvement of the inflammation followed by improvement of the dermatitis may be sufficient to persuade the reader.

Case No. 12

A six year old male with urticaria.

History: He used to suffer from urticaria without any apparent cause. Rash appeared in the evening or during the night for two to three hours. The patient had frequent dizziness, headache and nausea. He was diagnosed as having an orthostatic disorder after examination. Adenotomy was tried one year previously but brought no results.

2 Antibody-antigen reaction is explained as a biological reaction of protein or some complex particle, but we can observe that a simple stimulant (for example SO_2) or physical changes such as coldness may provoke allergic symptoms

3 If a biological reaction is considered as an antigen antibody reaction we cannot explain the occurrence of double reaction to different antigens.

4 Hyposensitization therapy is a treatment of allergy by repeated injection of antigen but it increases reagin Blocking antibody is confirmed, but it must be a treatment to make the body accustomed to a stimulant

5 The usefulness of the non specific therapy or the treatment of anti-chemical mediator may suggest an involvement of factors other than antigen-antibody reaction.

6 Nasopharyngeal treatment is applicable to any allergic symptoms and normalizes eosinophil leucocyte values It also influences serum immune globulin in the same manner as the hyposensitization treatment.

From the above observations we may conclude that an antigen antibody reaction may cause allergic symptoms, but it is not the exclusive reason As explained previously the nasopharyngeal treatment attained good results in nasal allergy responding to the alleviation of nasopharyngitis. From this fact nasal allergy is related to nasopharyngitis in a wider sense than antigen-antibody reaction.

Further investigation of the relation between nasopharyngitis and functional disorders of the nasopharynx is explained in Table 48 which includes the cases collected by TAKAYAMA. The table contains groups C and D in addition to B Group B consisted of 14 typical allergic cases with intracutaneous reaction, eosinophilia and positive clinical symptoms. Group C consisted of negative intracutaneous reaction but with clinically positive symptoms, and gorup D was all negative except for clinical symptoms (sniffling and nasal congestion) These 33 cases were treated exclusively by the nasopharyngeal therapy (1% $ZnCl_2$) and the results were good in all groups Besides these groups, hypertrophic rhinitis responded well to the treatment. Conchotomy has been used in a rhinitis chronica hypertrophica vasomotorica, but persistent relapse is a threat It often complicates nasopharyngitis but local treatment alone produces good results. Some patients often mistake nasopharyngeal abnormality as a stuffy nose. Since the disorder is not of a physical nature, clinical observation discloses normal findings and some clinicans might conclude that the patient had nasal neuritis. However abrasion treatment might satisfy the patient. The sensation of nasopharyngeal disorders should appear on the dorsal portion of the soft palate but it often radiates to the nasopharynx and makes the patient complain of nasopharyngeal abnormality or nasopharyngeal neurosis. Various types of nasal allergy (including the so-called vasomotor rhinitis) and habitual hypertrophy of the nasal mucosa usually complicates nasopharyngitis and local treatment often alleviates the allergic symptoms. From this observation we may find a causual relationship in nasopharyngitis and the functional disorders of the nose.

Effect of the Nasopharyngeal Therapy in Other Allergic Diseases

From the clincial observation of allergic rhinitis we often observe complication of the

3 Nasopharyngitis as a Source of Stimulation of the Autonomic Nerve

In the section on the basic study of nasopharyngitis, w explained that nasopharyngeal stimulation provokes a contraction of the pulse w e t the finger and the extraordinary contraction gradually returns to normal in parallel with remission of the inflammation.

Nasopharyngeal stimulation also elevates the blood pressure, but it immediately returns t normal as observed in the blood pressure change caused by mecholyl injection If blood pressure changes result in type N after nasopharyngeal stimulation, mecholyl injection produces type N of blood pressure changes, etc Further we explained that in types S and P the abnormal blood pressure types will turn to normal in parallel w th the remission of nasopharyngeal inflammation.

The nasopharynx has a close relation w th the utonomic nerve systems and inflammation of the nasopharynx will affect the utonomic nerves. It is assumen that the nasopharyngeal cav ty has an important receptor for the autonomic nerve transmission. The naspoharynx is quite sensitive to utonomic nerve stimulation and the existence of inflammation will promote stimulant ffects and will react intensely t the utonomic nerve timulation.

Biological reaction to a repeated stimulation ma be considered another important factor reducing the threshold of the utonomic nerve. Foreign stimulants may not provoke allergic reaction t first but repetition of stimulation gradually produces hypersensitu ty I reverse this action has been considered useful treating hypersensitivity of the utonomic nerve system. The relation between nasopharyngitis and the utonomic nerves can only be understood when tonomic nerve disorders respond to nasopharyngeal treatment

Nasopharyngeal treatment has unexpected clinical results the treatment of symptoms originating from utonomic nerve disorders as shown below

1 dizziness or vertigo
2. orthostatic dysregulation (O.D)
3. hypotension
4 hypertension
5 allergy
6. neurosis (like enuresis)
7 gastric ulcer

Headache and diabetes mell tus were excluded intentionally

1) Dizziness or Vertigo

The thor formed that most cases of dizziness have latent inflammation in the nasopharynx and dizziness may be improved by the local treatment of nasopharyngitis as the nflamma tion of the nasopharynx subsided.

Dizziness is associated with autonomic nerve disorders and this is commonly believed to be true, but only a few persons believe t is a fact actually confirmed by evidence Various tests ha e been devised to demonstrate causal re lationships between autonomic nerve disorders and the associates symptoms.

As explained already the nasopharyngeal treatment exercised control over the autonomic nerve system Nasopharyngeal stimulation ex tends the contraction time of the pulse wa e t the peripheral portion of the fingers from 15 seconds t several hundreds seconds according to the indi idual constitution. Prolonged con traction time suggests that the person has arious autonomic nerve disorders such as palpitation headache, thermoparaesthesia and gastrointestinal symptoms. On the other hand contraction time of the pulse wave is often re lated t the degree of nflammation of the nasopharynx. The local treatment of the nasopharynx generally restores peripheral essel contraction to normal almost permanently And normalization of the plethysmogram and the

Clinical course: He complained of severe pain and intense bleeding was observed. The continuous treatment of 1 ZnCl$_2$ produced marked improvement and in one week no bleeding was observed. After two weeks the abrasion pain disappeared.

On the 5th day the symptoms of urticaria were improved. The site of the rash was limited and the pruritic sensation was reduced. About the 10th day he experienced few symptoms and after three weeks almost none. During the treatment he had rash on the neck and extremities but the symptoms soon disappeared after the treatment. During the course of the treatment he had no urticaria for three months and the local treatment was suspended. A month later he had a slight rash around the neck after he ate shrimp.

The treatment was resumed for one month and he was then free from urticaria for three years.

Case No. 13

A 55 year old female with atopic dermatitis.

Chief complaint: Susceptibility to sumac (lacquer) poisoning.

History: The patient suffered from sumac poisoning at the age of 17 and she found herself constitutionally susceptible to it thereafter. She got a rash whenever she touched poison sumac or lacquered ware such as bowels, chopsticks or other utensils. When the patient was 50 years old she was susceptible to colds. Tonsillectomy was neffective.

Clinical course: Nasopharyngeal examination disclosed a severe abrasion pain and bleeding indicating the presence of intense inflammation in the nasopharynx. 1 ZnCl$_2$ twice weekly was prescribed for the local treatment. All other medications were discontinued. After the treatment she never caught cold and was never confined to bed. Her appetite improved and her constipation was cured. Hypotensive condition was improved. It is interesting to note that the patient had contact dermatitis which was completely cured in six months. She was susceptible to poison sumac, but after the treatment she could touch it without reaction. Since then she did not have any rash if she touched lacquered utensils.

From these findings we may assume that the influence of nasopharyngitis is not limited to neighboring organs. To clarify the correlation is a problem to be solved in the future but for the time being reduction of 11 OHCS in the allergic onset is an improtant clue to the solution.

Significance of Nasopharyngitis in the Treatment of Allergic Diseases

Let us consider the mechanism of allergic symptoms apart from the antigen-antibody reaction. Nasopharyngitis exists latently in a large number of people and its exacerbation or improvement continues daily. A common cold is the worst case and a complication of nasal symptoms is called acute catarrhalic rhinitis. Clinically it closely resemble to allergic rhinitis except that catarrhalic rhinitis is (1) not chronic, (2) lacking eosinophil leucocytes and (3) free from antigen antibody reaction.

Acute rhinitis usually terminates after several days but occasionally patients catch cold while in bed. Such a relapse or exacerbation of cold is always accompanied by acute aggravation of nasopharyngitis. Acute recurrences of nasopharyngitis can be observed frequently in pediatric patients.

At first the symptoms of acute rhinitis show the typical pattern of the disease but repeated recurrence lowers the susceptibility threshold and the onset of nasal symptoms becomes facilitated. A transformation of allergic symptoms from the chronic rhinitis is commonly observed. (Such phenomena can be observed in other diseases. An infant with chronic common cold which was always associated with thrombopenia was treated by nasopharyngeal abrasion and the chronic cold was completely crued. Since then no thrombopenia was observed. The patient, if left untreated, might have been developed some serological disease.)

As stated in the previous pages, habitual rhinitis can be eliminated without difficulty but negligence might lead to hypersensitivity of the nasal mucosa despite the slightness of the initial symptoms. The author believes that allergies should be regarded as hyperreactivity symptoms. Thus antigen-antibody reaction or eosinophilia could be understood as one process of hyperreaction. (The activity of the chemical mediator produced by antigen-antibody reaction should never be denied in any way.)

Cutaneous Diseases

Lupus erythematodes or atopic dermatitis were cured by the treatment of nasopharyngitis. For the same reason pustulosis, scleroderma, urticaria and alopecia were improved after the treatment of nasopharyngitis. The author eliminated case reports because of scarcity of cases.

3 Nasopharyngitis as a Source of Stimulation of the Autonomic Nerve

I the section on the basic study of nasophryngitis, w explained that nasopharyngeal stimulation provokes a *contraction of the pulse wa e t the finger* and the extraordinary contraction gradually returns to normal in parallel with remission of the inflammation.

Nasopharyngeal stimulation also elevates the blood pressure, but t immediately returns to normal as bserved in the blood pressure change caused by mecholyl injection. If blood pressure changes result in type N after nasopharyngeal stimulation, mecholyl njection produces type N of blood pressure changes, etc. *Further* w explained that in types S and P the abnormal blood pressure types will turn to normal in parallel w th the remission of nasopharyngeal inflammation.

The nasopharynx has a *close relation* w th the autonomic nerve ystems and inflammation of the nasopharynx will affect the autonomic nerves. It is assumen that the nasopharyngeal cav ty has important receptor for the utonomic nerve transmission. The naspoharynx is quite sensitiv to a tonomic nerv stimulation and the existence of inflammation will promote stimulant effects and will react intensely to the utonomic nerve timulation.

Biological reaction to repeated stimulation may be considered *another important factor* reducing the threshold of the a tonomic nerve. Foreign stimulant ma not provoke allergi reaction t first, but repetition of stimulation gradually produces hypersensitivity. In reverse this action ha been considered useful in treating hypersensitiv ty of the a tonomic nerve system. The relation between nasopharyngitis and the utonom nerves can only be understood when tonomic nerv d sorders respond to nasopharyngeal treatment.

Nasopharyngeal treatment has unexpected linical results the treatment of symptoms originating from utonomic nerve disorders as shown below

1. dizziness or ertigo
2. orthostatic dysregulation (O D)
3. hypotension
4. hypertension
5. allergy
6. neurosis (like enuresis)
7. gastri ulcer

Headache and diabetes mellitus were excluded tentionally.

1) *Dizziness = Vertigo*

The uthor formed that most cases of dizziness ha latent nflammation in the nasopharynx and dizziness may be improved by the local treatment of nasopharyngitis as the inflammation of the nasopharynx subsided.

Dizziness is *associated* w *th utonomic nerv* disorders and this is commonly believed to be true but only a few persons believe t is a fact *actually confirmed by evidence*. Various *tests* have been devised t demonstrate causal re lationships between utonomic nerve disorders *and the associated symptoms*.

As explained already the nasopharyngeal treatment exercised control over the autonomic nerv system. Nasopharyngeal *stimulation* extends the contraction time of the pulse wa e t the peripheral portion of the fingers from 15 seconds to several hundreds *seconds according to* the indi idual constitution. Prolonged contraction time suggests that the person has various utonom nerve *disorders such as* palpitation headache thermoparaesthesia and gastrointestinal symptoms. On the other hand, contraction time of the pulse wave is *often* related to the degree of nflammation of the nasopharynx. The local treatment of the nasopharynx generally restores *peripheral vessel contraction* to normal almost permanently And normalization of the plethysmogram and the

Clinical course He complained of severe pain and intense bleeding was observed. The continuous treatment of 1% $ZnCl_2$ produced marked improvement and in one week no bleeding was observed. After two weeks the abrasion pain disappeared.

On the 5th day the symptoms of urticaria were improved. The site of the rash was limited and the pruritic sensation was reduced. About the 10th day he experienced few symptoms and after three weeks almost none. During the treatment he had rash on the neck and extremities but the symptoms soon disappeared after the treatment. During the course of the treatment he had no urticaria for three months and the local treatment was suspended. A month later he had a slight rash around the neck after he ate shrimp.

The treatment was resumed for one month and he was then free from urticaria for three years.

Case No. 13

A 55 year old female with atopic dermatitis.

Chief complaint Susceptibility to sumac (lacquer) poisoning.

History The patient suffered from sumac poisoning at the age of 17 and she found herself constitutionally susceptible to it thereafter. She got a rash whenever she touched poison sumac or lacquered ware such as bowls, chopsticks or other utensils. When the patient was 50 years old she was susceptible to colds. Tonsillectomy was ineffective.

Clinical course Nasopharyngeal examination disclosed a severe abrasion pain and bleeding indicating the presence of intense inflammation in the nasopharynx. 1% $ZnCl_2$ twice weekly was prescribed for the local treatment. All other medications were discontinued. After the treatment she never caught cold and was never confined to bed. Her appetite improved and her constipation was cured. Hypotensive condition was improved. It is interesting to note that the patient had contact dermatitis which was completely cured in six months. She was susceptible to poison sumac, but after the treatment she could touch it without reaction. Since then she did not have any rash if she touched lacquered utensils.

From these findings we may assume that the influence of nasopharyngitis is not limited to neighboring organs. To clarify the correlation is a problem to be solved in the future but for the time being reduction of 11-OHCS in the allergic onset is an improtant clue to the solution.

Significance of Nasopharyngitis in the Treatment of Allergic Diseases

Let us consider the mechanism of allergic symptoms apart from the antigen-antibody reaction. Nasopharyngitis exists latently in a large number of people and its exacerbation or improvement continues daily. A common cold is the worst case and a complication of nasal symptoms is called acute catarrhalic rhinitis. Clinically it closely resemble to allergic rhinitis except that catarrhalic rhinitis is (1) not chronic (2) lacking eosinophil leucocytes and (3) free from antigen antibody reaction.

Acute rhinitis usually terminates after several days but occasionally patients catch cold while in bed. Such a relapse or exacerbation of cold is always accompanied by acute aggravation of nasopharyngitis. Acute recurrences of nasopharyngitis can be observed frequently in pediatric patients.

At first the symptoms of acute rhinitis show the typical pattern of the disease, but repeated recurrence lowers the susceptibility threshold and the onset of nasal symptoms becomes facilitated. A transformation of allergic symptoms from the chronic rhinitis is commonly observed. (Such phenomena can be observed in other diseases. An infant with chronic common cold which was always associated with thrombopenia was treated by nasopharyngeal abrasion and the chronic cold was completely crued. Since then no thrombopenia was observed. The patient, if left untreated, might have been developed some serological disease.)

As stated in the previous pages, habitual rhinitis can be eliminated without difficulty but negligence might lead to hypersensitivity of the nasal mucosa despite the slightness of the initial symptoms. The author believes that allergies should be regarded as hyperreactivity symptoms. Thus antigen antibody reaction or eosinophilia could be understood as one process of hyperreaction. (The activity of the chemical mediator produced by antigen antibody reaction should never be denied in any way.)

Cutaneous Diseases

Lupus erythematodes or atopic dermatitis were cured by the treatment of nasopharyngitis. For the same reason pustulous, sclerodermia, urticaria and alopecia were improved after the treatment of nasopharyngitis. The author eliminated case reports because of scarcity of cases.

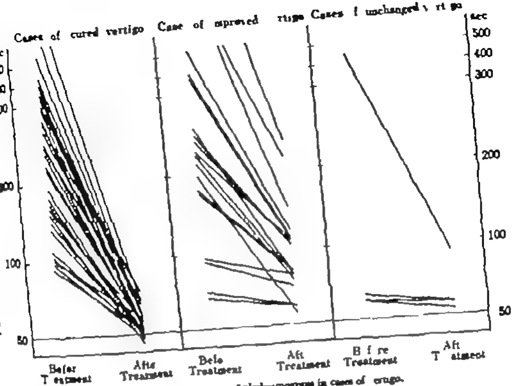

Fig. 60. Improvement of plethysmograms in cases of vertigo.

Table 51 Percentage of cases cured of vertigo as observed by type of change of the blood pressure.

Type of change of blood pressure	No. of cases before treatment of nasopharyngitis	Cured	Improved	Unchanged
S type	34	20 (59%)	12 (35)	2 (6)
P type	6	6 (100%)	0	0
N type	14	6 (42%)	6 (42%)	2 (16%)

to dizziness those which belong to types P and S were cured at a higher rate. In contrast, 14 cases of type N indicated poor cure rate as compared to other types.

The assessment of cure of dizziness responding to the nasopharyngeal treatment was made by measuring changes of pulse wave in the finger and the types of blood pressure alteration after the nasopharyngeal abrasion. The cure by the local treatment may be considered due to irritation of the autonomic nerve which was caused by presence of inflammation in the nasopharyngeal cavity.

Table 52 demonstrates the clinical value of nasopharyngeal treatment in patients with dizziness. The patients were subjected to a caloric test before the treatment. The evaluation of the efficacy was made on 35 DP cases, 21

Table 52 Result of the nasopharyngeal treatment in dizziness classified according to vestibular function.

Caloric test	Number of cases	Cured	Im-proved	Un-changed
DP	35	28 (80%)	3	4
CP	21	12 (57%)	8	1
Normal	29	22 (73%)	5	2

Total	87	63	17	7

Table 49 Vertigo.

Cured		Improved		Unchanged	
3 cases	(50%)	3 cases	(50%)	0	
1	(25)	2	(50%)	1 cases	(25)
6	(75)	2	(25)	0	
[illegible]	(56%)	7	(44%)	0	
10	(90%)	1	(10)	0	
2	(22%)	4	(44%)	3	(34%)
31	(58%)	19	(35%)	4	(7)

remission of autonomic nerve disorders are closely related.

The possibility of clinical application was tested by FURUYA on 54 cases of dizziness of unknown etiology The nasopharynx of all patients was examined and every one of them had nasopharyngitis The nasopharyngeal treatment with 1 / $ZnCl_2$ solution brought complete cure to 31 cases, improvement of symptoms in 19 cases and 4 cases remained unimproved. The efficacy was 92 6% Table 49 illustrates the results more precisely Efficacy ratings were classifies as complete cure allevia tion of symptoms and unchanged Correspond ing to the symptoms naspoharyngeal inflamma tion was divided into intense medium and mild. The bottom row of the table indicates the number of cures. The highest cure rate was observed in the patients with intense nasopharyn gitis (22 cases) and next in those with medium nasopharyngitis. The four unchanged cases inculded 2 mild cases and one with intense nasopharyngitis. The above observation indi cates that dizziness was improved in higher percentage when the nasopharyngeal inflammation were severe. Table 50 shows the length of contraction time of the pulse wave measured before and after treatment of nasopharyngitis in 45 patients and the value of the treatment for dizziness. The left column shows the contraction time of the pulse wave caused by the stimulation of the nasopharyngeal cavity Before the treatment [illegible] patients had a pulse contraction time of more than 500 seconds and 83 / or 45 cases showed a prolonged contraction time of over 100 seconds. There was no case that had contraction time less than 50 seconds. After the treatment the contraction time was reduced to 300 seconds or less and 44 cases were below 100 seconds.

As indicated in the Table 31 cases were cured 19 improved and 4 cases unchanged. Three out of six cases that had a contraction time of over 500 seconds before the treatment had been cured completely and in the remaining cases dizziness was improved. 29 cases of cure were from the group exceeding 100 seconds and 3 unsuccessful cases belonged to the group of less than 100 seconds. Fig 60 shows the cure rate of dizziness. All of the cured cases show that the plethysmogram returned to normal but in the improved cases the plethysmogram did not always become normal

Table 51 shows the types of blood pressure curve of 54 cases with dizziness before tand after nasopharyngeal treatment Before the nasopharyngeal treatment, 34 cases were type S and 6 type P and 14 cases type N After the treatment 44 cases were type N (normal) 7 type S and there were no types P With regard

provement as shown in the diagram and she returned home after three months treatment. No symptoms have been observed until now.

It seems that the case might be a mere psychogenic disease, but if nasopharyngitis had not been detected, it might have been diagnosed as of unknown etiology. Furthermore, if no objective improvement had been observed, the local treatment might have been considered kind of suggestion therapy. Nasopharyngitis has an important relation with the autonomic nerve system, and the fact that autonomic disorders can be improved by nasopharyngeal treatment represents an amazing medical progress (Tables 54, 55).

2) Orthostatic Dysregulation (OD)

The symptoms of orthostatic dysregulation are related to dizziness which originates in postural unbalance. It might be considered reasonable to include "O.D." in the category of diseases with dizziness or vertigo, but in general both symptoms have slightly different meanings. Certain cases of orthostatic dysregulation are not associated with dizziness" and in most cases complications of hypotension, allergic disorders, gastrointestinal impairments will mask the presence of orthostatic abnormality. In this respect the diagnosis of orthostatic dysregulation is almost impossible without the involvement of nasopharyngitis. Orthostatic dysregulation is observed in infants and in middle aged women and the latter cases it is often diagnosed as hysteria or menopausal disorder. In school children almost 10% are said to have this symptom. Despite the importance of this symptom in the pediatric

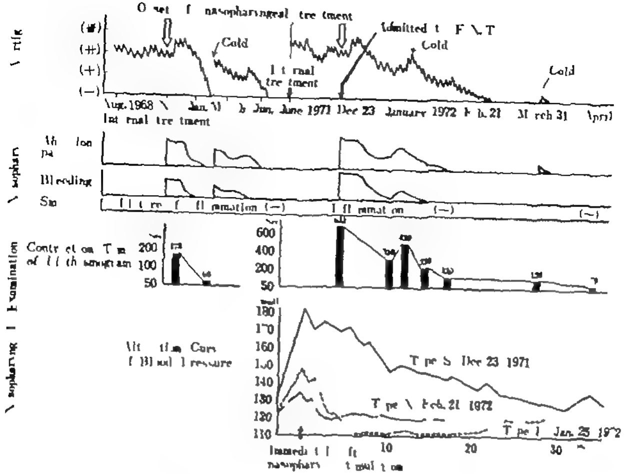

Fig 61 Case No. 14 36 y.o. F

CP cases 29 normal cases and 2 cases of hyper function. Of 35 DP 28 cases were cured (80) 3 cases alleviated and 4 cases unchanged. The CP group showed 12 cases of cure (57) and 75% of cure rate was obtained in normal group. The rate of cure in the CP group is rather low as compared with that of other groups. However no cases needed surgical operation because of severe symptoms. In the following a case report of dizziness is described.

Case No. 14

A 36 year old house wife with dizziness.

Chief complaint Rotary vertigo, palpitation and pain in the chest.

History No Specific illness. The symptoms appeared four years ago and were diagnosed as "autonomic ataxia" and medication was prescribed for three months.

There was no improvement.

She visited an ORL clinic and minor inflammation in the nose was found but no abnormality was detected. After two months she visited our clinic (3 years and 6 months ago).

Acoustic nerve test was normal, but severe nasopharyngitis was observed. The nasopharyngeal abrasion was carried out and she once developed intense inflammation but gradually recovered during treatment four times a week. Complete cure was achieved after 8 months treatment. She had no relapse for two years since then. About one year and six months ago she developed symptoms again after exacerbation of nasopharyngitis. On account of dyspnoe she was admitted to an emergency hospital. She was diagnosed as having autonomic ataxia and cardioneurosis. For half a year various treatments were tried but no improvement was made. She visited our clinic again and we detected the presence of intense nasopharyngitis.

Clinical finding The autonomic nerve test was made by means of nasopharyngeal stimulation and a typical autonomic nerve disorder was detected. Fortunately we had the patient record as shown in Fig 61. Table 53 and the clinical course of nasopharyngitis corresponded exactly to improvement of autonomic nerve disorder.

On the 5th day of the treatment pain in the chest disappeared and on the 10th day no rotary sensation was felt. The autonomic nerve disorder and nasopharyngitis showed marked im-

provement as shown in the diagram and she returned home after three months treatment. No symptoms have been observed until now.

It seems that the case might be a mere psychogenic disease, but if nasopharyngitis had not been detected, it might have been diagnosed as of unknown etiology. Furthermore if no objective improvement had been observed, the local treatment might have been considered a kind of suggestion therapy. Nasopharyngitis has an important relation with the autonomic nerve system, and the fact that autonomic disorders can be improved by nasopharyngeal treatment represents an amazing medical progress (Tables 54, 55).

2) Orthostatic Dysregulation (OD)

The symptoms of orthostatic dysregulation are related to a „dizziness" which originates in postural imbalance. It might be considered reasonable to include "O.D." in the category of diseases with dizziness or vertigo, but in general both symptoms have slightly different meanings. Certain cases of orthostatic dysregulation are not associated with „dizziness" and in most cases complications of hypotension, allergic disorders, gastrointestinal impairments will mask the presence of orthostatic abnormality. In this respect the diagnosis of orthostatic dysregulation is almost impossible *without the involvement of nasopharyngitis.* Orthostatic dysregulation is observed in infants *and in middle aged women and the latter cases* *It is often diagnosed as hysteria or menopausal* disorder. *In school children almost 10%* are said to have this symptom. Despite the importance *of this symptom in the pediatric*

Table 54 Degree of complication of nasopharyngitis and the results of treatment of vertigo (All are complication cases).

Cases of nasopharyngitis	Vertigo Cured	Improved	Unchanged

Moderate	8	7	2
Mild	1	2	1
	31	19	4

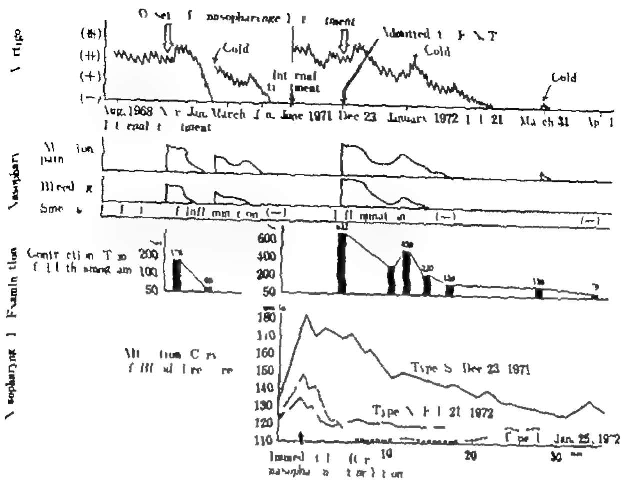

Fig. 61 Case No. 14 36 y.o. F

CP cases, 29 normal cases and 2 cases of hyper function. Of 35 DP 28 cases were cured (80 %), 3 cases alleviated and 4 cases unchanged. The CP group showed 12 cases of cure (57 %) and 75% of cure rate was obtained in normal group. The rate of cure in the CP group is rather low as compared with that of other groups. However no cases needed surgical operation because of severe symptoms. In the following a case report of dizziness is described.

Case No. 14

A 36 year old house wife with dizziness.

Chief complaint: Rotary vertigo, palpitation and pain in the chest.

History: No Specific illness. The symptoms appeared four years ago and were diagnosed as "autonomic ataxia" and medication was prescribed for three months.

There was no improvement.

She visited an ORL clinic and minor inflammation in the nose was found but no abnormality was detected. After two months she visited our clinic (3 years and 6 months ago).

Acoustic nerve test was normal but severe nasopharyngitis was observed. The nasopharyngeal abrasion was carried out and she once developed intense inflammation but gradually recovered during treatment four times a week. Complete cure was achieved after 8 months treatment. She had no relapse for two years since then. About one year and six months ago she developed symptoms again after exacerbation of nasopharyngitis. On account of dyspnoe she was admitted to an emergency hospital. She was diagnosed as having autonomic ataxia and cardioneurosis. For half a year various treatments were tried but no improvement was made. She visited our clinic again and we detected the presence of acute nasopharyngitis.

Clinical finding: The autonomic nerve test was made by means of nasopharyngeal stimulation and a typical autonomic nerve disorder was detected. Fortunately we had the patient's record as shown in Fig. 61, Table 53 and the clinical course of nasopharyngitis corresponded exactly to improvement of autonomic nerve disorder.

On the 5th day of the treatment pain in the chest disappeared and on the 10th day no rotary sensation was felt. The autonomic nerve disorder and nasopharyngitis showed marked im-

ment of the symptoms, and in these cases the nasopharyngeal abrasion treatment will produce marked effects.

Case No. 15

An 8 year old school boy with O.D.

Chief complaint Headache

History Frequent headache and chronic repetition of fever. Headache occurs twice or three times a month and the patient tires easily, chronic snuffles. O.D. was diagnosed at the pediatrician's. Adenoidectomy was performed two years previously but no improvement was achieved. Reasons for visiting pediatric department:

1. Always pale and inactive. Frequent visits to the doctor.
2. Easily gets tired and soon loses interest in drawing or handicraft lessons.
3. Physically unstable and occasionally shouts with a queer voice.
4. Often uses the word "uninteresting".
5. Easily catches cold and is absent from school with fever of 37–38°C.

Clinical findings No specific changes in ORL. A nasopharyngeal abrasion caused severe pain which lasted for half a day. Marked postabrasive hemorrhage. The smear specimen disclosed medium scale exfoliation of ciliated epithelium, with swelling of the cytoplasm. A small amount of lymphocytes and pavement epithelium were observed.

Clinical course All medications previously used were discontinued and application of 1% $ZnCl_2$ was exercised daily.

1st day Marked abrasion pain and hemorrhage.

10th day Abrasion pain and postabrasive hemorrhage were improved and the patient regained his activity. He used to feel tension in the head although headache was absent, but the sensation of heavy head was much improved. *Snuffles remained as usual.*

20th day The sensation of heavy head was improved. No more tiredness. He sat at his desk to study of his own accord.

30th day Again caught cold and complained of headache. The nasopharyngeal abrasion caused severe pain and bleeding. (*Intense* inflammation developed whenever he caught cold.) The author is of the opinion that acute nasopharyngitis with the complication of autonomic nervous disorders should be called a "common cold". The postabrasive pain continued for half a day. Serous rhinorrhea continued half a day. Snuffles increased.

35th day Abrasion pain and bleeding still intense. Headache was present. The usual treatment was continued.

45th day The abrasion pain and bleeding alleviated. The patient said that he felt good. Remission of headache and the heavy feeling were obtained.

50th day A letter from the patient's mother described his marked recovery.

80th day Almost no complaint, but it was decided to continue treatment once weekly.

department or in school health no medical solution has been considered. Orthostatic dysregulation in children occurs with various clinical patterns and cannot be diagnosed by simple criteria. It looks like a neurotic disease because of its multiple symptoms. In order to provide standard diagnostic criteria, the following criteria are specified.

To determine the diagnosis, orthostatic dysregulation should have the following elements

1. Indication of 1 major symptom and 3 minor symptoms
2. Indication of 2 major symptoms and 1 minor symptom
3. Indication of 3 major symptoms

Diagnostic Criteria for Orthostatic Dysregulation

Major symptoms

- A Dizziness or vertigo often occur
- B Uncomfortable feeling when standing. In severe cases the patient falls down
- C Uncomfortable sensation while taking a bath or hearing bad news
- D Palpitation or short breathing frequently occur
- E. Difficulty in getting up in the morning and poor condition in the morning

Minor symptoms

- a Palor
- b Poor appetite
- c Occasional abdominal pain
- d Tired feeling or weak feeling
- e Frequent headache
- f *Susceptibility* to vehicle vertigo
- g Decrease of pulse pressure in excess of 16 mmHg by the standing test.
- h. Alteration of systolic blood pressure over 21 mmHg by the standing test
- i Increase of pulse rate over 21 in one minute.
- j Lowering of over 0.2 mV in T I and T II in orthostatic ECG

The so-called orthostatic dizziness or vertigo does not always occur in orthostatic dysregulation. It is doubtful whether these symptoms belong to autonomic nerve disorders.

However as explained in the Basic Study of *nasopharyngitis* in relation to extension of contraction time in the pulse wave of the fingertip the orthostatic disorder can be considered to have some relation to nasopharyngitis.

The symptoms of orthostatic dysregulation such as a fainting sensation when standing have close relations with the hypersensitiveness of the autonomic nerves as diagnosed through the pulse wave pattern in the fingertip. If we develop this concept we might be able to consider nasopharyngitis as a focus of inflammation which stimulates the autonomic nerves to cause orthostatic dysregulation. With this concept we observed the nasopharynx of the school children who had orthostatic dysregulation. Nasopharyngeal observation revealed the presence of intense inflammation (erosion) and local treatment achieved complete cure of the orthostatic symptoms. Adenoidectomy is a useful treatment for orthostatic disorders but the result does not always warrant improve

Fig. 63. Nasopharyngeal smear after the treatment.

Fig. 64. Smear of upper esophagus before the treatment.

pharynx developed medium size flushing and minor tenderness at the right side of the cavity. Adenoidectomy and tonsillectomy were carried out at age of 7. A small amount of pus was detected in the nasopharynx. Microscopic examinations disclosed marked redness all over the cavity which was especially heavy in the dorsal portion of the soft palate extending to the palatine arch. The nasopharyngeal mucous was abrased with cotton applicator. Severe abrasion pain and bleeding were complained of which indicated the presence of intense nasopharyngitis. The smear specimen, showing traces of bleeding, included exfoliation of ciliated epithelium, which was swollen and transformed, and number of wandering leucocytes and lymphocytes were recognized. Infectious bacteria included staphylococcus aureus and other strains. The inflammation was shown to be in highly erosive state.

The upper end of the esophagus was examined with the cotton applicator. Some bleeding and pain were observed. The smear specimen indicated the intense exfoliation of epithelium and wandering leucocytes. Staphylococci aureus were present in the focus of inflammation.

Clinical course. The nasopharyngeal mucosa and the upper end of the esophagus were treated with 1 $ZnCl_2$ every day. The applicator was inserted through the soft palate, especially the

School children are generally susceptible to the common cold and the symptoms are usually severer than those of adults.

The main symptoms of the above cases were the so-called diencephalon syndrome or autonomic dystonia for which no specific methods of treatment have been found It is clinically of interest to observe the cure by means of nasopharyngeal abrasion. The author considers that stimulation of the nasopharynx will relate to the hypothalmus and cause vasomotor contraction or alteration of blood pressure The presence of intense inflammation in the mucus of the nasopharynx is stimulated by the passing of air inhaled from the outside the passing of air always gives stimulations and results in autonomic ataxia O D and diencephalon syndrome If exacerbation of nasopharyngitis is caused by air pollution it is reasonable to consider that a great many autonomic disorders occur due to nasopharyngeal inflammation Table 56 is a consolidated list of 12 cases of O D The significant characteristic of this table is that all cases were treated exclusively by local treatment In the past O D had been considered a difficult disease and no specific treatment except administration of autonomic nerve sedatives has been exercised At least 8 out of 12 cases were cured by means of the nasopharyngeal treatment alone

Orthostatic dysregulation (O D) is not rare in adults In children more cases were found among boys, and in adult cases females of middle age exceeded the males. When females reach the age of menopause their symptoms of O D are confused with menopausal symptoms. The following case is of a middle-aged woman who complained of innumerable symptoms and despite various treatments no results had been achieved

Case No. 16 (Figs. 62-66)

H Y A female 35 years old. Continuous slight fever and neurosis.

Chief complaint Continuous slight fever headache, aching of both sides of the neck, stiff neck, insomnia, lack of appetite gastric ptosis and hypotension.

History She complained of slight fever and headache since three years before and the fever had continued for six months up to the present. (ASL-O and CRP were negative.) Three years previously she had migrane, a pain in the both sides of the neck, a stiff neck and she had been troubled by insomnia and anorexia. After examination by an internist she was diagnosed as having mild gastric ptosis and hypotension (100-65mmHg)

Various medications were tried but in vain symptoms were exacerbated and she was always in bad humor She visited a psychiatrist but no abnormal EEGs were recorded. She visited many doctors but no one diagnosed her illness.

Clinical finding E.N T examinations were normal except for a slight swelling in the nasopharynx. An abrasion with a cotton applicator caused severe abrasion pain in the right side of the nose and bleeding but mild inflammation was noted in the left side of the nose. The naso-

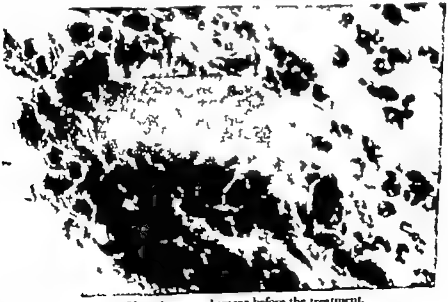

Fig 62. Nasopharyngeal smear before the treatment.

Fig. 63. Nasopharyngeal smear after the treatment.

Fig. 64. Smear of upper esophagus before the treatment.

pharynx developed medium size flushing and minor tenderness at the right side of the cavity. Adenoidectomy and tonsillectomy were carried out at age of 7. A small amount of pus was detected in the nasopharynx. Microscopic examinations disclosed marked redness all over the cavity which was especially heavy in the dorsal portion of the soft palate extending to the palatine arch. The nasopharyngeal mucosa was abraded with cotton applicator. Severe abrasion pain and bleeding were complained of which indicated the presence of intense nasopharyngitis. The smear specimen, showing traces of bleeding, included exfoliation of ciliated epithelium, which was swollen and transformed, and number of wandering leucocytes and lymphocites were recognized. Infectious bacteria included staphylococcus aureus and other strains. The inflammation was shown to be in highly erosive state.

The upper end of the esophagus was examined with the cotton applicator. Some bleeding and pain were observed. The smear specimen indicated the intense exfoliation of epithelium and wandering leucocytes. Staphylococci aureus were present in the focus of inflammation.

Clinical course. The nasopharyngeal mucosa and the upper end of the esophagus were treated with 1% $ZnCl_2$ every day. The applicator was inserted through the soft palate, especially the

Fig 65. Smear of upper esophagus after the treatment.

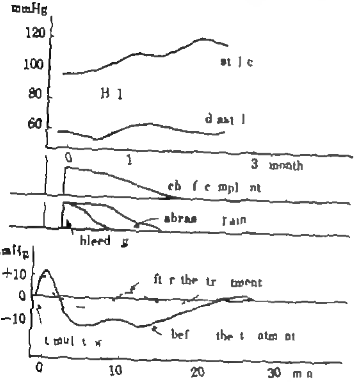

Fig. 66. Case No. 18. E. Y. 32y. o. F

dorsal portion, and reached th nasopharyngeal ca ty Esophagus insertion was attained passing through the ppl shape cavity The right side wall produced pain and bleeding The first application of the swab caused pain which lasted for four hours and transient excretion of nasal fluid was observed. The pain was felt at th esophageal wall but no bleedi g was observed. The next day she had a good sleep and alleviation of night sweat. The fever began to reduce and on the 15th day it became normal.

She could not believe the recovery since she had been annoyed by persistent fever for three years. After that day she trusted the treatment, and other symptoms which persisted for many ears were gradually improved. Abrasion pain and bleeding of the nasopharyngeal ca ty were alleviated on the 7th day and bleeding ceased on the 9th day Abrasion pain disappeared on the 13th day and after the 14th day headache in the right side of the head was completely cured. The nasophary geal abrasion reduced the pain

and bleeding after the 13th day of the treatment and the frontal headache (corresponding to the dorsal portion of the soft palate) gradually reduced and finally disappeared on the 16th day of the treatment.

Abrasion of the tonsils produced bleeding, but on the 11th day no bleeding was observed. On the 27th day stiffness of the neck was healed and all of Siebeck's syndrome disappeared. She left the clinic after 44 days of treatment.

She has been visiting this clinic once every week and she has not had the symptoms for two years. The comparison of pre-post treatment is tabulated as follows

	Pretreatment	Posttreatment
Nasopharyngeal abrasion	Marked exfoliation of ciliated epithelium. Presence of large number of lymphocytes and wandering leucocytes.	Normal condition
Plethysmogram of the finger	Contracted for several hours	Normal
Blood pressure curv	P type	N type
Fibrinolysis	351 minutes	161 minutes
Siebeck's symptoms	Night sweat, cold sensation, palpitation, vertigo, headache, constipation and diarrhea	All disappeared

It is interesting to note that alterations of the peripheral pulse wave and blood pressure curve were observed after the stimulation by nasopharyngeal abrasion.

The initial pulse wave showed unlimited contraction (several hours of observing contraction was continued but it did not return to the normal state) but returned to normal after 40 days treatment. The blood pressure alteration pattern was initially of the cholinergic type but was later modified to the N type. Corresponding to normalization of the autonomic disorder symptoms, which were 7 in all, all vanished. Sedation of autonomic disorders may be possible for a time with medication, but generally it is impossible to normalize the condition permanently.

Discovery of a useful treatment for autonomic nerve disorders, which have been considered subjective and psychological phenomena, has endowed the medical world with the possibility of an active cure by means of local treatment.

We experience many cases like this at the clinic and nearly all the cases gained good results from the nasopharyngeal treatment alone. The following is another case with various complaints.

Case No. 17

A.T. A 47 year old female complaining of atypical symptoms.

Chief complaints Paroxysmal pain in the postoperative abdomen. Headache. Stiffness of the neck. Palpitation. Cold sensation of the limbs. Vertigo. Diarrhea and toothache.

History She was hypersensitive by nature. She was operated on for appendicitis at the age of 33, and thereafter she complained of habitual abdominal pain. Surgical treatments had been made but failed to produce any improvement. Then she developed gastric pain, diarrhea, paraesthesia of the hands and feet associated with palpitation, dizziness, headache, stiffness of the neck, etc. Recently she was diagnosed as having hysteria by a neighboring internist. She further developed a severe pain in the maxilla (in several teeth and the gums) and the other symptoms were exacerbated.

Clinical findings She had several lesions on the abdomen as a result of the surgical treatment, but XP revealed no abnormal picture. No histological changes were apparent in the maxilla but a severe inflammation was present in the nasopharynx.

The local treatment produced severe pain and bleeding. The finger pulse wave showed a prolonged contraction. The nasopharyngeal treatment was tried and obtained the following results

Clinical course Immediately after the initial treatment, the patient showed systemic hypersensitiveness and had severe toothache. Every portion of the skin was irritable and she complained of tension in the head. She said she was not herself. It seemed as though all symptoms which had previously existed were exacerbated. After the nasopharyngeal treatment she could not move and had to lay down for two hours. In spite of unfavorable conditions, the treatment was continued. After one month she was rid of the headache, gastric pain, dizziness, cold sensation in both limbs, diarrhea and stiffness of the neck. Continuous treatment produced step by step an improvement and three months later every symptom was cured and disappeared. After two years she visited the clinic. She was active and cheerful and looked healthy.

The case may belong to other territory than autonomic disorders, but, the concept of the nasopharyngeal tretment of autonomic dystonia is applicable.

Fig 65. Smear of upper esophagus after the treatment.

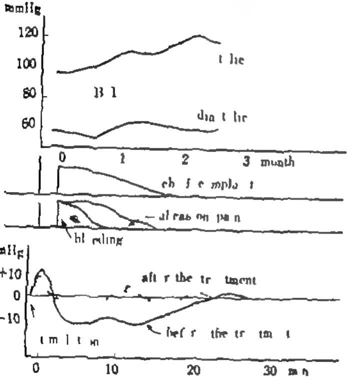

Fig 66. Case No. 18. E. Y. 32 y. o. F

dorsal port on, and reached the nasopharyngeal cavity Esophagus insert on as ttained passing through the appl shape ca ty The right side wall produced pain and bleed ng The first application of the swab caused pain which lasted for four hours and transient excretion of nasal fluid was observed. The pain was f lt t the esophageal wall, but no bleeding was observed. The next day she had a good sleep and alleviation of night sweat The fever began to reduce and on the 15th day t became normal.

She could not believe the recovery since she had been annoyed by persistent fever for three years. After that day she trusted the treatment and other symptoms which persisted for many years were gradually improved. Abrasion pain and bleeding of the nasopharyngeal ca ty were alleviated on the 7th day and bleeding ceased on the 9th day Abrasion pain disappeared on the 13th day and after the 14th day headache in the right side of the head was completely cured The nasopharyngeal brasion reduced the pain

occasionally dizziness. An internist diagnosed hypotension.

Clinical findings: Blood pressure was 90–60 mmHg. Routine ORL examination revealed no abnormality. Insertion of the cotton applicator into the nasopharynx (passing through the nasal side and from the nasopharynx) and abrasion of the dorsal portion of the upper soft palate provoked severe pain and marked bleeding. She was confirmed as having intense erosive nasopharyngitis. The smear specimen obtained from the swab evidenced marked inflammation. Apparent exfoliation of ciliated epithelium, appearance of wandering leucocytes and proliferation of infectious micro-organisms were detected. The case was confirmed as typical latent nasopharyngitis. Immediately after the local abrasion, the blood pressure pattern showed P type.

Treatment: The cotton applicator dipped into 1% $ZnCl_2$ solution and small amount of Xylocain, was applied to the nasopharynx, particularly to the dorsal portion of the upper palate and all other treatments and medication were discontinued in order to examine the exclusive efficacy of the nasopharyngeal treatment.

On the 10th day of the treatment abnormal feeling of the nasopharynx vanished and the abrasion pain and bleeding gradually alleviated on the 3rd day of the treatment. On the 10th day of the treatment all such symptoms disappeared. Blood pressure was elevated slightly to 100/70mmHg.

On the 20th day the further elevation was achieved and the patient maintained the level (110/70mmHg) (Fig. 67). The examination of the blood pressure curve at this time showed that patient belonged to type N (similar to the pretreatment status).

The nasopharyngeal treatment thus always produces normalization of blood pressure and is applicable to the hypotensive patients. In the hypotensive case, the lowering normalization of blood pressure takes more time as compared with that of diastolic phase (Figs 68, 69). We examined the curve of ambulatory patients (9 cases) which showed that 7 cases responded well to the treatment. Among the treated groups, 2 cases failed to respond to the treatment. They discontinued the treatment after two weeks (Fig 68). It might be that the expected result would have been obtained if they had continued the treatment.

Hypertension

Examination of the nasopharynx of the

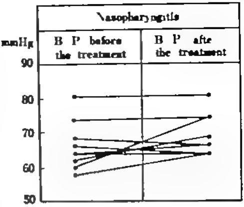

Fig. 68. Improvements of diastolic blood pressure.

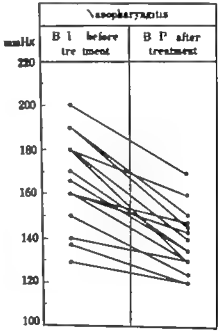

Fig. 69. Improvements of systolic blood pressure.

hypertensive patients always disclosed the presence of severe nasopharyngitis. The continuous local treatment gradually lowered the blood pressure to normal standard as observed in the hypertensive cases. In the hypertensive cases blood pressure types of NSBP as shown in the hypotensive cases, belonged mostly to S or P type, but they changes to N type when they responded to the nasopharyngeal treatment. The clinical courses of both cases resemble each other and in this respect the author considered hypertension and hypotension belong to the same category of disease. We examined the

Table 57 Pathological alteration of the blood pressure.

9	32	♀	P	90/60	110/74	3 weeks

3) Nasopharyngeal Treatment and Changes in the Blood Pressure Curve

Nasopharyngela treatment produced immediate and apparent changes of blood pressure. As the reason for hypertension or hypotension in the presence of an intense inflammation in the nasopharyngeal cavity it may be considered that stimulative air always passes through the nasal cavities giving constant stimulation to the mucosa of the nose and the constant stimulation produces elevation or lowering of blood pressure.

A primary consideration was that after stimulation of the nasopharynx blood pressure type P (lowering type) might have caused hypotension and the type S (elevating type) for hypertension. Actual examination disclosed that this pattern was not true

Nevertheless, there were not many N types and most of them belonged to either S or P which were related to autonomic imbalance The local treatment of nasopharyngitis reduced hypertension and elevated blood pressure in hypotensive patients. In the following the author describes the cases of hypotension and hypertension separately

Hypotension

Hypotension is frequently complicated by autonomic disorders and patients frequently complain of symptoms such as gastroptosis orthostatic vertigo and tiredness. Hypotension is often observed in middle aged women and often causes confusion of diagnosis with menopausal disorders. In short hypotension is a unknown etiology without any effective treatment. Many hypotensive patients, because of scarcity of symptoms, have been left untreated The author investigated the hypotensive cases in relation to neurotic complications. Examination of the nasopharynx showed that without exception they had inflammation of the nasopharynx. As usual the nasopharyngeal treatment was applied. Amazing enough all cases, more or less produced elevation of blood pressure.

Case No. 18 (Fig 67)

E.Y 32 year old female with hypotension (essential)

Chief complaint Stiff neck, abnormal feeling of the nasopharynx, vertigo, gastric ptosis.

History She complained of abnormal feeling since the seven years previously She also complained of stiff neck, slight gastric ptosis and

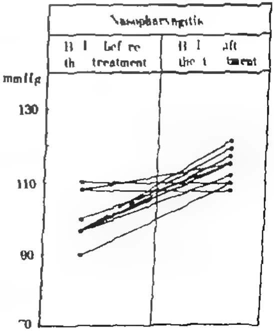

Fig. 67 Improvements of systolic blood pressure.

That is, cotton applicator dipped in 1% $ZnCl_2$ was inserted into the dorsal portion of the upper soft palate through the nasopharynx arch. The clinical course is demonstrated in Fig. 72. It is worth nothing that the clinical course of the improvement in blood pressure corresponded to the improvement of nasopharyngitis.

As indicated in the diagram, the duration of observation was 7 months. The patient visited the clinic once or twice annually to measure the blood pressure. After complete normalization, exacerbation of nasopharyngitis was not associated with an elevation of the blood pressure. However it is hoped that the hypertensive patient will consult the doctor at an early stage of the disease for nasopharyngeal treatment.

As the author felt it was interesting another case is described below

Case No. 29 (Fig. 73)

M.W. A 30 year old female with essential hypertension.

Chief complaint Headache. Hypertension.

History She had complained of headache, nasal congestion and rhinorrhea since she was 17 years old.

About 6 years ago she got hypertensive during her first pregnancy (170–120mmHg). After the child birth blood pressure returned to normal. When she was pregnant three years ago, her blood pressure began to rise in the 7th month of pregnancy and the condition never improved after the childbirth. Hypotensives were prescribed but with no effect. Exacerbation of headache and nasal congestion made her to come to our clinic.

Clinical findings Blood pressure 170–120 mmHg. No protein was found in urine. Examination of internal medicine did not show any abnormality. Routine ORL showed that she had slight hypertrophy in the inferior turbinate body and slightly serous rhinorrhea. No other changes were observed. The nasopharyngeal abrasion test disclosed a severe pain and bleeding as indication of an intense inflammation. The smear specimen indicated the presence of intense erosive inflammation in the nasopharynx, with the appearance of number of wandering leucocytes, proliferation of bacteria and exfoliation and transformation of ciliated epithelium. NSBP was 5.

Clinical course: Administration of hypotensive drugs was discontinued except the local application with 1% $ZnCl_2$ solution (with small amount of anaesthetic added). The improvement is shown in Fig. 74. The initial hypertensive value, 170–120mmHg, returned to 148–114mmHg and on the 10th day of the treatment the improvement reached 148–110mmHg. On the 20th day all other symptoms, headache, nasal congestion and rhinorrhea disappeared. (Hypertensive patients used to complain of headache and stiff neck. In the past these symptoms had been considered to be due to hypertension. The author postulates these symptoms might be derived from nasopharyngitis or the presence of inflammation at the upper end of the esophagus and the pain might be the dispersion of these inflammations.)

The postabrasive bleeding vanished on the 10th day and the smears became normal on the 25th day. The exfoliation of ciliated epithelium was reduced. The wandering leucocytes and infectious micro-organisms were almost absent from the site. On the 40th day the systolic blood pressure reached 130–98mmHg, which was 20mmHg lower than the initial value. The treatment was discontinued but the measurement of blood pressure always indicated 130–100mmHg. The NSBP pattern indicated N type after the treatment.

T ble 58 Cases of Hypotension Type changes of NSBP before and after treatment.

Type of NSBP (Nasopharynx stimulation blood pressure)	Treatment of nasopharyngitis	
	before	fter
S Type	3 (33)	1 (11)
P Type	4 (44)	1 (11)
N Type	2 (23)	7 (78*)

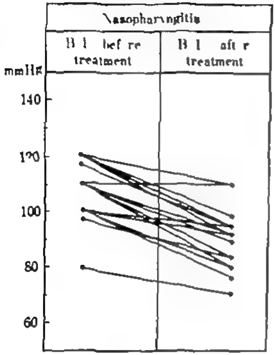

Fig 70. Improvements of diastolic blood pressure

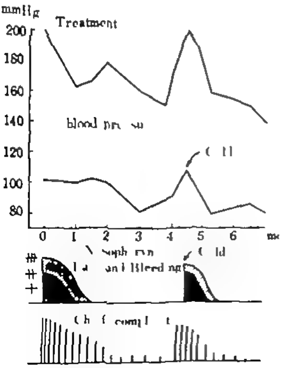

Fig 71 Case No. 19 Hypertension(F.M 54 y o. F)

curve of 15 patients of hypertension which showed that all cases responed well to the treatment (Figs. 69 70)

Case No 19 (Fig 71)

F M. A 54 year old female with essential hypertension.

History She caught cold three years ago. Since that time she felt abnormality in the throat. She was diagnosed as having hypertension and various treatments were tried but in vain. She feared that she had cancer of the nasopharynx and visited our clinic.

She had 200mmHg of systolic pressure and 100mmHg of diastolic. She complained that the increase of abnormal feeling seemed to correspond to an elevation of blood pressure.

Clinical findings A physical examination disclosed that she had renal and hepatic impairment. AP of the heart indicated hypertrophy of the left venticle but the symptom was not severe. She was diagnosed as having essential hypertension. Routine ENT examination failed to detect any abnormality but the nasopharyngeal abrasion test disclosed a marked inflammation in the nasopharynx. She complained of intense abrasion pain and bleeding The smears showed marked exfoliation and transformation of ciliated epithelium and proliferation of micro-organisms.

Clinical course All other medications and treatment were discontinued except application of the cotton applicator to the local inflammation.

History An intense headache in the forehead had occurred since four years previously was especially severe during the afternoon and evening. Sleep was disturbed and the patient was admitted to psychiatry department for the treatment of insomnia. In spite of two years of treatment no effect was obtained. Because of nasal congestion and rhinorrhea, the patient visited our clinic.

Clinical observation A little nasal fluid was observed in the nasopharyngeal cavity but there were no abnormal findings. X-ray showed no changes in the paranasal sinus, and the throat culture showed no existence of pus. Sinusitis was denied. Insertion of the cotton applicator through the nasopharynx produced severe abrasion pain and bleeding. A severe inflammation was recognized at the dorsal portion of the soft palate. When the swab passed through the nasopharyngeal portion severe pain eradiated to the forehead

Note The author found that anesthesia of the dorsal portion of the soft palate occasionally reduced pain in the head, but many years passed before he realized the relationship between headache and nasopharyngitis.

Clinical course The day after the treatment the patient showed good response to the treatment and alleviation of the pain was attained. He used to use sleep inducing drugs because of fear of insomnia. On the 25th day of the treatment he was able to terminate the use of the drug. A headache was felt in the afternoon.

The symptom completely disappeared on the last day. When he travelled by train headache again occurred. Abrasion pain returned, but after week of the treatment the abrasion pain disappeared and the symptom was also cured.

The treatment was continued for two months and perfect cure was attained. There are a great number of similar cases but they responded well to the treatment. Duration of the symptoms varies, some within three weeks while others had persistent headache for over 10 years. In any case the local abrasion treatment cured them perfectly

Most patients complained of dizziness while they were in a crowd. This is considered to be the result of stimulation by dust affecting the

4 Relation between Nasopharyngitis and Pain in the Head and Neck Region

Nasopharyngitis in most cases is latent and the patients do not complain of local symptoms, but it often produces pain No one has ever considered participation of nasopharyngitis when the patient has a pain or unusual sensory disorders of unknown etiology This is because the existence of nasopharyngitis has been completely ignored by the medical profession but the treatment of this disease has improve dvariuos diseases of unknown origin

The major categories of pain are included in the following list

1 Headache
2 Stiff neck
3 Cervical pain
4 Abnormal sensation in the throat
5 Toothache and gum pain

Other pains are neuralgia rheumatism and gout which can be cured by nasopharyngeal treatment

1) Headache

Headache is still unknown as to its mechanism and etiology HOC Committee of N I H classified the headache as shown in Table 39

T ble 39 Classification of headache

1 headach of migraine type
  A. classic migraine
  B. common migraine
  C cluster migraine
  D hemipleg and ophthalmolog migraine
  E. lower half" headache
2 muscle contraction headach
3. combined heada he vascula and muscle construc tion
4 headache of nasal vasomotor reaction
5 headach of delusional, con ersion or hypochondrial tates
6 non-migrainous vascula headaches
7 traction headache
8. headache due to cranial flammation
9 13 headaches due to diseases of ocula aural, nasal and sinus dental or other cranial or neck structures
14 cranial neuritides
15. cranial neuralgias

There are various classifications, but vasomotor and contraction headache is associated with the severest pain. Clinically headache is classified as familial headache, adenoide headache or Thornwaldt s headache and so on. Since the old days many clinicians have ideas concerning the etiology but none with persuasive data

Headache as examined from the aspect of nasopharyngeal inflammation may give an advangageous solution The author may say headache is a referred pain originating at the nasopharyngeal site Headache as classified according to the site of onset can be listed as frontal pain temporal pain parietal pain and occipital pain. There exist inflammation sites corresponding to the site of headache and the treatment of the inflammation can cure headache with 100 % effectiveness. A simple anesthetic treatment of inflammation site produced an analgesic effect though transient The corresponding points are illustrated below (Fig 78)

Frontal	Dorsal portion of the soft palate occasionally agger nasi
Occipital portion	Dorsal cavity of the nasopharynx (Adenoids)
Temporal	Dorsal half of the inferior nasal meatus, the left or right side
Parietal	Upper portion of the nasopharyngeal cavity

A greater number of headaches of unknown origin can be treated by the local abrasion of the corresponding site of an inflammation except when the cause is clearly confirmed

Frontal Pain

Case No. 21

A 24 year old male Frontal headache

Table 64. Cases of the temporal pain.

No.	Age	Sex	Onset of illness	Grade	Time/day	Side wall of the inferior meatus: Abrasion	Side wall of the inferior meatus: Bleeding	Duration of treatment	Effect
24	52	♀	2 eeks before	light	continuous	+	—	5 days	cured
[illegible]	40	♂	7 years	severe	turning points of the seasons	++	++	5 days	cured
26	19	♀	5–6 years	moderate	afternoon~evening	++	++	3 weeks	cured
27	36	♀	2 years	moderate	2–3 hours	+	+	2 weeks	cured
28	23	♂	4–5 years	severe	morning	++	#	20 days	cured

30	45	♀	6 months	moderate	continuous	++	++	2 weeks	cured

neck pain eradiates to the occipital portion. He visited an internist and orthopedic surgeon but no abnormality was diagnosed. No nasal symptom was observed.

Clinical findings: The nasal mucosa showed slight redness but there were no adenoids and no abnormal findings in the dorsal portion of the nasopharynx. An abrasion of the nasopharyngeal site produced severe pain and bleeding. The patient explained that the pain was like thrusting to the occipital portion of the head. The abrasion test indicated no severe inflammation.

Clinical course: For the first ten day the abrasion pain and bleeding were severe and no alleviation of the pain was attained. On the 15th day the abrasion pain and bleeding abated and on the 20th day all the symptoms disappeared. Since then no recurrence was reported.

T ble 63 shows six randomly selected cases. In contrast to the above case, they responded well to the treatment and the cure was achieved in a comparatively short period. Relation of occipital pain and inflammation of the dorsal portion of the nasopharyngeal ca ity has been explained frequently. Adenoids and Thornwaldt headache were described by the i estigators in the past. Headache originating from the adenoids was improved by adenoidectomy. Headache of adenoid origin often occurs in the occipital portion, but not alway so. Adenoidectomy can cure inflammation t the dorsal portion of the nasopharynx but abrasion t the time of operation or local anaesthesia may cure nasopharyngitis. Thornwaldt headache is observed in the occipital portion only. Bursa pharyngeae may exist in he dorsal portion of the nasopharynx and the induction of pain is called "Thornwaldt headache". However the lack of Bursa may also cause occipital pain as a pattern of nasopharyngitis.

The uthor intentionally selected two cases here because he considers it might be unacceptable to postulate symmetric relationship between inflammation and pain. The finding was obtained finally after a search for the cause of pain. Considering the correlation existing in occipital headache, the author at first considered inflammation t the side wall of the nasopharynx, but later it was found that inflam

autonomic nerve reflex or changes of vasomotor activity in the cranium (Refer to dizziness and nasopharyngitis.) Headaches of hypertensive patients are not always related to the elevated blood pressure. Exacerbation of nasopharyngitis may explain the reason. Table 60 demonstrates the results of the treatment in 17 randomly selected cases who complained of forehead pain which was cured by means of the nasopharyngeal treatment but no medication was exercised. The table includes 4 cases of sinusitis. As sinusitis is considered a cause of headache the author tried to eliminate the case. Sinusitis may become an indirect cause but the author has to examine more cases before he decides the causal relationship. Table 61 shows a comparison of the grade of pain and the degree of inflammation (according to the severity of abrasion pain). All cases had moderate to severe nasopharyngitis and the degree of the headache ran parallel to the severity of the inflammation. As shown in Table 62 the length of the treatment and the alleviation of the headache does not associate each other. Case No 5 was cured of the headache, which had persisted for over 10 years, in one week, while No 12 had to take four months treatment to attain complete cure. In general most patients responded to the treatment in two or three weeks and complete cure was attained within the period.

Occipital Pain

Case No 2?

A 27 year old male with occipital pain.

History He complained of dryness of the nose without any reason since four or five years previously. Occipital pain developed especially severe when he bent over. When he picked the

slight moderate severe

mation at the site had caused otalgia The causation of pain at the temporal was found to respond after moving the probe forward, i e. to the side wall of the meatus nasi inferior The symmetric relation was quite close and all cases attained cure within a short period (Table 31) In some cases the opening of the meatus nasi inferior was insufficient and insertion of the cotton applicator was difficult. The inferior nasal concha must be treated surgically to enable sufficient application of the local treat ment The symmetric relationships of head ache and the site of nasopharyngeal inflam mation are described and the number of days required for complete cure are tabulated in Tables 65 66 and 67

As shown, 74 of cure (24 out of 32) was attained within three weeks and 15° in one month but there were only 3 cases that took over one month for treatment. The above 32 cases are unrelated to sinusitis, which has been considered an important causal factor of headache. Deformity of the septum was also considered to cause headache but we did not give special consideration to the treatment of the deformity and local abrasion was carried out.

Temporal pain

The temporal pain has more clear cut cor respondence with inflammation because of the locality If the pain occurs to the left side the inflammation is found in the left upper portion of the meatus nasi inferior and does not cor respond to inflammation existing in any other site. Inflammation at the corresponding site will have a severe abrasion pain and bleeding The smears reveal inflammation at the site. We often observe disappearance of pain after simple application of local anaesthesia (Table 64)

Case No. 23 (Fig 73)

S.K. A 25 year old male w th pain in the temporal region.

History Th patient had severe pain in the right side of the head without any apparent cause. The stinging pain was almost intolerable. An oculist discovered impairment of vision and rectifying eyeglasses were prescribed but in vain. Later he had sl ght nasal congestion and visited an ORL clinic for the treatment of sinusitis but no improvement was achieved. Then he visited our clinic

Clinical observations Sl ght deformity of the septum was observed in the right nose. The nasal mucosa was faintly red, but no bnormality

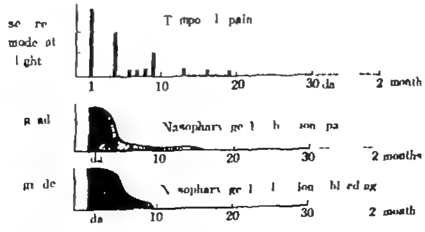

Fig. 73. Case No. [illegible] (S.K. 25 y o. M.) Case of the right temporal pain.

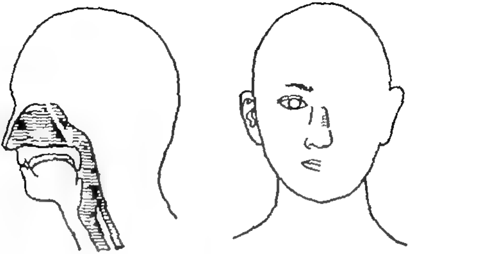

Fig. 76. Radiated headache.

was observed in the meatus. X-ray and probing examination denied sinusitis. The right meatus nasi inferior was rubbed with cotton swab along the upper portion, and intense pain and bleeding were observed. The smears revealed marked inflammation after the culture.

The usual treatment with 1 $ZnCl_2$ relieved the pain. 2 xylocain and 1 $ZnCl_2$ were used for the treatment and other medication was discontinued.

Clinical course was indicated in Fig. 73.

As shown, severe pain disappeared on the day after the treatment and the patient drunk to the bottom next day.

The pain recurred after four days and the continuous treatment completely cured the migrain. The bleeding which had been observed until the 5th day of the treatment discontinued thereafter.

Case No. 24

K.U. A 9 year old girl with temporal pain.

History The pain had been persisten for four to 6 years. When she was tired pain was severe. She was given analgesics. An internist and orthopedic surgeon discovered no abnormality. Familial headache was recorded.

Clinical observations Routine ENT examination disclosed no abnormality. A slight rash and abrasion pain were recognized, but severe abrasion pain was was complained of at the left meatus nasi inferior.

With the passing of the swab she complained of severe pain which radiated towards the left side head. Marked bleeding at the site was noted.

Clinical course Treatment with 1 $ZnCl_2$ (for the first one or two day xylocain was previously applied) was employed. No improvement was obtained on the day after the treatment. On the 3rd day of the treatment headache subsided, and gradually disappeared. No analgesics were used on the 10th day of the treatment. Three weeks of treatment cured her headache. The abrasion pain and bleeding disappeared on the 7th day of the treatment.

2) Pain other than Headache

Pains occur in the face, shoulder neck and ear. The author sought for the original sites of inflammation and the referred pain, and obtained following symmetric correlations.

Pain in the neck (unusual sensation) ↔ *Palatine tonsil (chronic tonsillitis)*

Otalgia ↔ Pharyngeal orifice of auditory tube

Stiff neck ↔ Upper part of the esophagus

Facial pain ↔ Base of the nasal cavities

3) Paraesthesia in the Lateral Neck

Pain or hyperesthesia in the lateral neck is often explained in relation to stimulation or dislocation of the cervical vertebra, or by the term "cervical syndrome". The author has no sufficient data for the hypothesis, but, he considers it is worth taking into account the participation of chronic tonsillitis. The author has discussed the methods to confirm the presence of inflammation which caused headache.

1. The smear specimen (to examine exfoliation of epithelial cells, wandering cells and proliferation of micro-organisms)
2. Abrasion pain
3. Postabrasive hemorrhage

slight moderate severe

mation at the site had caused otalgia The causation of pain at the temporal was found to respond after moving the probe forward i e to the side wall of the meatus nasi inferior The symmetric relation was quite close and all cases attained cure within a short period (Table 31) In some cases the opening of the meatus nasi inferior was insufficient and insertion of the cotton applicator was difficult The inferior nasal concha must be treated surgically to enable sufficient application of the local treatment The symmetric relationships of headache and the site of nasopharyngeal inflammation are described and the number of days required for complete cure are tabulated in Tables 65 66 and 67

As shown 74% of cure (24 out of 32) was attained within three weeks and 15% in one month but there were only 3 cases that took over one month for treatment. The above 32 cases are unrelated to sinusitis, which has been considered an important causal factor of headache Deformity of the septum was also considered to cause headache but we did not give special consideration to the treatment of the deformity and local abrasion was carried out

Temporal pain

The temporal pain has more clear cut correspondence with inflammation because of the locality If the pain occurs to the left side the inflammation is found in the left upper portion of the meatus nasi inferior and does not correspond to inflammation existing in any other site Inflammation at the corresponding site will have a severe abrasion pain and bleeding The smears reveal inflammation at the site We often observe disappearance of pain after simple application of local anaesthesia (Table 64)

Case No 23 (Fig 75)

S.K. A 25 year old male with pain in the temporal region

History The patient had severe pain in the right side of the head without any apparent cause. The stinging pain was almost intolerable. An oculist discovered impairment of vision and rectifying eyeglasses were prescribed but in vain. Later he had slight nasal congestion and visited an ORL clinic for the treatment of sinusitis but no improvement was achieved. Then he visited our clinic.

Clinical observations Slight deformity of the septum was observed in the right nose The nasal mucosa was faintly red, but no abnormality

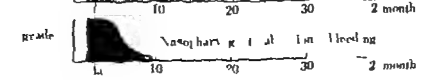

Fig. 75. Case No. 23 (S.K. 25 y. o. M.) Case of the right temporal pain.

and needed daily massage. She was told that she had intense stiffness in the neck. (Stiffness observed is caused by esophagitis and the improvement of the disease immediately relieves the patient of the stiff neck.) An internist and gynecologist diagnosed climacteric disturbances. Hormone treatment was prescribed but produced no effects. The patient had nasopharyngitis but was free from any other disorders. Unusual feeling of the esophagus was absent and no abnormalities were found in the cervical vertebrae.

Clinical findings Insertion of pharyngeal swabs in the esophagus produced sharp pain, especially the right wall which was symmetric to the site of stiff neck. The sharp pain produced by the swab abrasion passed through to the right side of the neck.

Post abrasion hemorrhage was observed and the symptom suggested cancer at the entrance of the esophagus. Epithelial cells in the smears were inspected microscopically and marked inflammation was detected by the presence of large number of neutrophilic leucocytes, wandering cells, exfoliation of deformed epithelial cells and proliferation of bacteria. However no cancer cells were observed.

Clinical course The local treatment was carried out while preparing the tissue section for pathological examination.

The treatment was carried out with 1 % $ZnCl_2$ solution every day. Rapid improvement was obtained and on the 5th day of treatment almost no bleeding was observed. On the 11th day abrasion pain was gone and the stiff neck was completely healed.

About 6 months later she caught cold and developed stiff neck in the left side. The esophageal abrasion caused marked bleeding. The usual treatment attained the disappearance of the stiffness in one week and no complaint has been heard from her since.

Localized esophagitis has been reported as a cause of esophageal neurosis but no reports have been published on stiff neck. Several reports on diagnosis of esophagitis did not describe precise clinical observations on esophageal changes, since no abrasion preparations were examined. Bono investigated the relations between abrasion preparations and localized esophagitis.

Stiff neck is explained in relation to cervical syndrome. The cause of syndrome is ascribed to dislocation of cervical vertebrae but the author considers esophageal inspection should be carried out first. Certain cases of clinically confirmed dislocation of cervical vertebra did not respond to stretch treatment but were successfully cured by the local abrasion treatment. Several cases with tangled relations were observed. A symmetric inflammation of the esophagus related to chronic tonsillitis, and the inflammation further influences the localized nasopharyngitis, which is derived from deformed nasal septum. (Reference is made to the Basic Study on symmetric relationships between inflammation and ORL disorders.)

6) **Facial Pain (Trigeminal Neuralgia)**

The term "trigeminal neuralgia" implies an anatomical relation to the trigeminus nerve reflex, but clinically it is not always so. The author tried to locate the site of inflammation of the nasal mucosa corresponding to the pain spot in the face, and found the inflammation at the agger nasi, meatus nasi medius and the base of the nasal cavities. (Inflammation is meant to be the site of lesion only confirmed by swab abrasion and the severity is judged by the degree of bleeding and abrasion pain.)

Case No. 26

H.S. A 20 year old girl with facial pain.

History About a month before the patient felt pricking pain in the right cheek extending to the whole face. Also headache in the right forehead. Since then the pain was induced whenever she inhaled cool air, became tired or while she was in an irritable condition, but did not occur while in a warm room. (It was winter when she visited our clinic.) When the pain was severe nausea and vomiting attacked her. She occasionally complained of right otalgia. About 15 days before she had been admitted to the hospital and diagnosed as having trigeminal neuralgia, but no treatment alleviated the pain.

Clinical observations No abnormal changes were observed in the facial nerves. Blood and urine were normal. Pain was located at the right superior and inferior orbital foramen and at the root of the zygomatical arch. For 15 days internal medicine failed to produce any result and the patient was transferred to the ENT department.

No abnormality was obtained by routine ENT examinations.

Abrasion of the nasopharynx produced a sharp pain which lasted for 3 hours with vomiting and nausea. However the pain at the right cheek and aural pain completely disappeared.

The treatment was continued to the next day but other medication was discontinued. The abrasion pain subsided and no bleeding was observed.

On the 5th day of treatment the abrasion pain

Also the author explained correlations between the smear preparation and the clinical pictures, such as abrasion pain and bleeding and a physician may confirm the progress of inflammation from observation of the smears. Diagnostic criteria for chronic tonsillitis are based usually on gross examinations, such as unclear lacunae, outlook, submerged tonsil and other changes that are visible to the eyes. The postoperative examinations often disclose intensive inflammation. Clinically chronic tonsillitis is frequently associated with tenderness and the author studied the cases shown in Table 68 Before the operation the degree of pain at both sites of the tonsils was recorded and the removed tonsils were examined pathologically for active inflammation especially of the difference of the size of lesion, which was compared with the pain recorded before the operation As demonstrated in Table 66 72% of the cases were found to be true to the postulation. The author used the nasopharyngeal cotton applicator and measured the grade of tenderness as a diagnostic criterion for chronic tonsillitis. The applicator produced a sharp pain at the symmetric site of inflammation and the local treatment may relieve the pain or paraesthesia of the side of the neck.

4) Abnormal Feeling in the Median Pharyngolaryngeal Region (Laryngeal Neurosis)

We have a large number of patients who complain of abnormal feeling at the median portion of the throat They are afraid of cancer but most cases were found to have nasopharyngitis after the nasopharyngeal abrasion test Acute nasopharyngitis usually produces dryness and ill sensation at the dorsal part of the soft palate and often causes nasopharyngeal pain. Acute tonsillitis generally has a unilateral nasopharyngitis whereas the pain related to nasopharyngeal disorder occurs regardless of the laterality

5) Stiff Neck as a Result of Cervical Esophagitis

As discussed already diagnosis of nasopharyngitis was made easy by (1) examination of the smear preparation (2) observation of abrasion pain and (3) bleeding This method facilitates the determination of diseases that are invisible. Inflammation of the esophagus cannot be observed even with esophagoscopy but this method of diagnosing nasopharyngitis may be applicable in the confirmation of the site of lesion. For abrasion of the esophageal orifice the nasopharyngeal applicator is employed and the swab is inserted to the esophagus passing through the piriform sinus and the side walls and other parts are abrased Previously prepare the median and inferior nasopharyngeal abrasion preparation and examine them. The swabs obtained from the nasopharyngeal tract can be easily distinguished from those collected from the esopharyngeal abrasion. No report has been published on esophageal inflammation in the past but the swab applied to the site generally reveals intense erosion with abrasion pain and bleeding Stiff neck is one of the referred symptoms of esophagitis. Relation between stiff neck and esophagitis have a close resemblance to those between nasopharyngitis and headache especially in unilateral stiff neck. The local abrasion at the site of lesion produces sharp and heterotopic pain in the neck Severe bleeding was apparent because the swabs were filled with blood The smear preparation disclosed marked degeneration and exfoliation of epithelial cells Proliferation of infectious micro-organisms and appearance of leucocytes are quite similar to cases of nasopharyngitis (All cases obtained normal findings after continuous nasopharyngeal treatment with 1 $ZnCl_2$ solution) Stiff neck can be palliated in parallel to alleviation of esophageal lesion

Case No. 25

A 43 year old housewife with unilateral stiff neck.

History She had severe stiff neck a year ago

and needed daily massage. She was told that she had intense stiffness in the neck. (Stiffness is observed if caused by esophagitis and the improvement of the disease immediately relieves the patient of the stiff neck.) An internist and gynecologist diagnosed climacteric disturbances. Hormone treatment was prescribed but produced no effects. The patient had nasopharyngitis but was free from any other disorders. Unusual feeling of the esophagus was absent and no abnormalities were found in the cervical vertebrae.

Clinical findings Insertion of pharyngeal swabs to the esophagus produced sharp pain, especially the right wall which was symmetric to the site of stiff neck. The sharp pain produced by the swab abrasion passed through to the right side of the neck.

Post abrasion hemorrhage was observed and the symptom suggested cancer at the entrance of the esophagus. Epithelial cells in the smears were inspected microscopically and marked inflammation was detected by the presence of large number of neutrophic leucocytes, wandering cells, exfoliation of deformed epithelial cells and proliferation of bacteria. However no cancer cells were observed.

Clinical course The local treatment was carried out while preparing the tissue section for pathological examination.

The treatment was carried out with 1 $ZnCl_2$ solution every day Rapid improvement was obtained and on the 5th day of treatment almost no bleeding was observed. On the 11th day abrasion pain was gone and the stiff neck was completely healed.

About 6 months later she caught cold and developed stiff neck in the left side. The esophageal abrasion caused marked bleeding. The usual treatment attained the disappearance of the stiffness in one week and no complaint has been heard from her since.

Localized esophagitis has been reported as a cause of esophageal neurosis but no reports have been published on stiff neck. Several reports on diagnosis of esophagitis did not describe precise clinical observations on esophageal changes, since no abrasion preparations were examined Bosso investigated the relations between abrasion preparations and localized esophagitis.

Stiff neck is explained in relation to cervical syndrome. The cause of syndrome is ascribed to dislocation of cervical vertebrae, but the author considers esophageal inspection should be carried out first. Certain cases of clinically confirmed dislocation of cervical vertebra did not respond to stretch treatment but were successfully cured by the local abrasion treatment. Several cases with tangled relations were observed. A symmetric inflammation of the esophagus related to chronic tonsillitis, and the inflammation further influences the localized nasopharyngitis, which is derived from deformed nasal septum. (Reference is made to the Basic Study on symmetric relationships between inflammation and ORL disorders.)

6) Facial Pain (Trigeminal Neuralgia)

The term "trigeminal neuralgia" implies an anatomical relation to the trigeminus nerve reflex, but clinically it is not always so. The author tried to locate the site of inflammation of the nasal mucosa corresponding to the pain spot in the face, and found the inflammation at the agger nasi, meatus nasi medius and the base of the nasal cavities. (Inflammation is meant to be the site of lesion only confirmed by swab abrasion and the severity is judged by the degree of bleeding and abrasion pain.)

Case No 26

H.S. A 20 year old girl with facial pain.

History About month before the patient felt pricking pain in the right cheek extending to the whole face. Also headache in the right forehead. Since then the pain was induced whenever she inhaled cool air became tired or while she was in an irritable condition, but did not occur while in warm room. (It was winter when she visited our clinic.) When the pain was severe nausea and omiting attacked her She occasionally complained of right otalgia. About 15 days before she had been admitted to the hospital and diagnosed as having trigeminal neuralgia, but no treatment alleviated the pain.

Clinical observations No abnormal changes were observed in the facial nerves. Blood and urine were normal. Pain was located at the right superior and inferior orbital foramen and at the root of the zygomatical arch. For 15 days internal medicine failed to produce any result and the patient was transferred to the ENT department.

No abnormality was obtained by routine ENT examinations.

Abrasion of the nasopharynx produced sharp pain which lasted for 3 hours with omiting and nausea. However the pain at the right cheek and aural pain completely disappeared.

The treatment was continued to the next day but other medication was discontinued. The abrasion pain subsided and no bleeding was observed.

On the 5th day of treatment the abrasion pain

Also the author explained correlations between the smear preparation and the clinical pictures such as *abrasion pain and bleeding* and a physician may confirm the progress of inflammation from observation of the smears. Diagnostic criteria for chronic tonsillitis are based usually on gross examinations, such as unclear lacunae outlook, submerged tonsil and other changes that are visible to the eyes. The postoperative examinations often disclose intensive inflammation. Clinically chronic tonsillitis is frequently associated with tenderness and the author studied the cases shown in Table 68. Before the operation the degree of pain at both sites of the tonsils was recorded and the removed tonsils were examined pathologically for active inflammation, especially of the difference of the size of lesion which was compared with the pain recorded before the operation. As demonstrated in Table 66 72 of the cases were found to be true to the postulation. The author used the nasopharyngeal cotton applicator and measured the grade of tenderness as a diagnostic criterion for chronic tonsillitis. The applicator produced a sharp pain at the symmetric site of inflammation and the local treatment may relieve the pain or paraesthesia of the side of the neck.

4) Abnormal Feeling in the Median Pharyngolaryngeal Region (Laryngeal Neurosis)

We have a large number of patients who complain of abnormal feeling at the median portion of the throat. They are afraid of cancer but most cases were found to have nasopharyngitis after the nasopharyngeal abrasion test. Acute nasopharyngitis usually produces dryness

Table 68 Tonsillitis and its tenderness.

and ill sensation at the dorsal part of the soft palate and often causes nasopharyngeal pain. Acute tonsillitis generally has a unilateral nasopharyngitis, whereas the pain related to nasopharyngeal disorder occurs regardless of the laterality.

5) Stiff Neck as a Result of Cervical Esophagitis

As discussed already diagnosis of nasopharyngitis was made easy by (1) examination of the smear preparation (2) observation of abrasion pain and (3) bleeding. This method facilitates the determination of diseases that are invisible. Inflammation of the esophagus cannot be observed even with esophagoscopy but this *method of diagnosing nasopharyngitis* may be applicable in the confirmation of the site of lesion. For abrasion of the esophageal orifice the nasopharyngeal applicator is employed and the swab is inserted to the esophagus passing through the piriform sinus and the side walls and other parts are abrased. Previously prepare the median and inferior nasopharyngeal abrasion preparation and examine them. The swabs obtained from the nasopharyngeal tract can be easily distinguished from those collected from the esopharyngeal abrasion. No report has been published on esophageal inflammation in the past but the swab applied to the site generally reveals intense erosion with abrasion pain and bleeding. Stiff neck is one of the referred symptoms of esophagitis. Relation between stiff neck and esophagitis have a close resemblance to those between nasopharyngitis and headache especially in unilateral stiff neck. The local abrasion at the site of lesion produces sharp and heterotopic pain in the neck. Severe bleeding was apparent because the swabs were filled with blood. The smear preparation disclosed marked degeneration and exfoliation of epithelial cells. Proliferation of infectious micro-organisms and appearance of leucocytes are quite similar to cases of nasopharyngitis. (All cases obtained normal findings after continuous nasopharyngeal treatment with 1 $ZnCl_2$ solution.) Stiff neck can be palliated in parallel to alleviation of esophageal lesion.

Case No. 28

S.K. A 46 year old male with dysacousis and diabetes.

Chief complaints Dysacousis, general for fatigue and urinary sugar

Diagnosis Diabetes and perceptive dysacousis.

History of disease The patient had dysacousis in both sides since 7 to 8 years previously which was worsened by total exhaustion. It was found by hearing test that membranes of the tympanum on both sides were almost normal, but the patient had slight salpingitis, auditory acuity by air conduction was 40dB on both sides and there was decrease in bone conduction. The patient was diagnosed as having perceptive deafness. (Dysacousis of this patient was abated by nasopharyngeal and otosalpingian treatments. Some kinds of perceptive deafness were treated so efficiently by nasopharyngeal and otosalpingian treatments especially in babies, which will not be mentioned here.)

Since glucose was found in the urine 3 years previously the patient underwent internal treatment by a specialist in diabetes. Though he was administered sulfonylurea (1/2 tablet of Tolinase) glucosuria was always positive. He had neither thirst nor leanness.

He was rather obese.

A few microaneurysms were found by an ophthalmoscopic examination. Blood glucose before the treatment was 136mg/dl.

Nasopharyngeal condition Nasal cavities and pharynx were normal and no abnormalities were observed. When the nasopharynx was stimulated, significant abrasive pain and slight hemorrhage were observed. Abrasive pain lasted for about 2 hours.

Treatment and progress 1% $ZnCl_2$ solution (with small amount of Xylocain) was applied to the nasopharyngeal wall every day

On the 1st day Severe pain when the solution was applied to the nasopharyngeal wall. Hemorrhage after $ZnCl_2$ application.

On the 2nd day Abrasive pain and hemorrhage. Glucosuria disappeared the day before.

On the 5th day As glucosuria became negative, drug administration was stopped.

On the 6th day Glucosuria appeared again. No drug administration.

On the 20th day Glucosuria was positive both in the morning and in the evening. Blood glucose was 87mg/dl 2 hours after meal.

Almost no abrasive pain when $ZnCl_2$ solution was applied to the nasopharynx.

On the 30th day Glucosuria was almost negative both in the morning and in the evening. Blood glucose was 78mg/dl.

On the 40th day Glucosuria was negative in morning and almost negative in the evening. Blood glucose was 120mg/dl.

On the 50th day; A few microaneurysms, which were observed previously disappeared completely by an ophthalmoscopic examination. Blood vessels were quite normal. Glucosuria was negative both in the morning and in the evening. Blood glucose was 80mg/dl.

On the 60th day Glucosuria was negative in the morning and in the evening. Blood glucose was 99mg/dl.

On the 70th day Glucosuria was negative in the morning and almost negative in the evening. Blood glucose was 84mg/dl. The nasopharyngeal treatment was interrupted for about 15 days

disappeared No onset of pain was recorded since the commencement of the treatment Follow-up treatment was continued for two months and she never developed pain

This is a successful case of nasopharyngeal treatment which stopped facial pain and otalgia The case shoed that pain originating from nasopharyngeal inflammation caused and otalgia instead of headache. In the facial pain abrasion pain extends over to the anterior edge of nasopharyngeal base and in the otalgia abrasion pain often takes place in the ostium of the auditory tube The inflammation at the nasopharyngeal base often appears as pain of unknown origin on the alveolar process of the maxillary bone. For this reason several pieces of teeth were extracted and cancer was suspected The patient was relieved of pain by the treatment of nasopharyngeal abrasion Particularly nasopharyngeal treatment is useful in the treatment of toothache. The author described how pain or uneasiness of unknown cause originated from the various inflammation sources. At the close of this chapter I would like to refer to certain cases involving blood pressure changes and neurosis.

Case No 27

A 51 year old female with complaints of left side migrain paraesthesia of the neck on the left side. Stiff neck on the left side. Pain in both knees. Systemic tiredness. Hypotension and irritability

History She was constitutionally weak and susceptible to colds. 10 years ago she developed symptoms and was diagnosed as having menopausal disorders and was given hormone preparations. No effect was attained. Menopause ended before 5 years but the symptoms were exacerbated Visited an orthopedic surgeon and was diagnosed as having a cervical syndrome. Traction therapy was tried for 8 months but no effect was attained. Recently the symptoms were aggravated and tinnitus developed. She visited the clinic.

Clinical observation Nasopharyngeal abrasion test exhibited intense bleeding and severe post abrasive pain which was heavier on the left side. High degree of deformity was observed in the left meatus nasal septum and the reason for severe symptoms on the left side was found. The tonsil had tenderness and postabrasive pain Esophageal application of a swab produced severe pain at the left side of the nasopharynx. A marked inflammation was observed in the left meatus nasal septum.

Clinical course Nasopharyngeal esophageal abrasion with the cotton applicator dipped into 1 $ZnCl_2$ reduced stiff neck and migrain on the 5th day of the treatment. After one month of continuous treatment the pain in both knees subsided and normal blood pressure was obtained. Generalized fatigue was gone and she could sleep well The patient continued treatment for 6 months and found that she had menstruation with the aid of hormone administration.

The psychological symptoms such as internal or psychiatric irritation are often complained of by the patients. They are so-called masked depression and the physician should remember the above case

5 Miscellaneous Facts Observed during the Course of Nasopharyngitis

1) Diabetes Mellitus

Diabetes is a disease considered to be incurable. Since it was found that diabetes was due to a defect of β-cells in Langerhans' islands, it became possible to control this disease and diabetic patients did not always become seriously ill. However the causes of diabetes are still unknown and its fundamental treatment has not yet been found.

The nasopharyngeal treatment, however seems to make it possible to treat this incurable disease. The mechanism, by which diabetes responds to the nasopharyngeal treatment, is not known yet. However it is certain that diabetic patients have nasopharyngitis, glucosuria disappears and blood glucose becomes normal by the local treatment of nasopharyngitis—exactly the same method prescribed in this paper. And as a result it becomes possible to stop administration of insulin and other drugs in some cases. Examples are given below.

Case No. 28

S.K. A 46 year old male with dysacousis and diabetes.

Chief complaints Dysacousis, general for fatigue and urinary sugar.

Diagnosis Diabetes and perceptive dysacousis.

History of diseases The patient had dysacousis on both sides since 7 to 8 years previously which was worsened by total exhaustion. It was found by a hearing test that membranes of the tympanum on both sides were almost normal, but the patient had slight salpingitis, auditory acuity by air conduction was 40dB on both sides and there was a decrease in bone conduction. The patient was diagnosed as having perceptive deafness. (Dysacousis of this patient was abated by nasopharyngeal and otosalpingian treatments. Some kinds of perceptive deafness were treated so efficiently by nasopharyngeal and otosalpingian treatments especially in babies, which will not be mentioned here.)

Since glucose was found in the urine 3 years previously the patient underwent internal treatment by a specialist in diabetes. Though he was administered sulfonylurea (1/2 tablet of Tolinase) glucosuria was always positive. He had neither thirst nor leanness.

He was rather obese.

A few microaneurysms were found by an ophthalmoscopic examination. Blood glucose before the treatment was 156mg/dl.

Nasopharyngeal condition Nasal cavities and pharynx were normal and no abnormalities were observed. When the nasopharynx was stimulated, significant abrasive pain and slight hemorrhage were observed. Abrasive pain lasted for about 2 hours.

Treatment and progress 1% $ZnCl_2$ solution (with a small amount of Xylocain) was applied to the nasopharyngeal wall every day.

On the 1st day: Severe pain when the solution was applied to the nasopharyngeal wall. Hemorrhage after $ZnCl_2$ application.

On the 2nd day: Absence of pain and hemorrhage. Glucosuria disappeared the day before.

On the 5th day: As glucosuria became negative, drug administration was stopped.

On the 6th day: Glucosuria appeared again. No drug administration.

On the 20th day: Glucosuria was positive both in the morning and in the evening. Blood glucose was 87mg/dl 2 hours after a meal.

Almost no abrasive pain when $ZnCl_2$ solution was applied to the nasopharynx.

On the 30th day: Glucosuria was almost negative both in the morning and in the evening. Blood glucose was 78mg/dl.

On the 40th day: Glucosuria was negative in morning and almost negative in the evening. Blood glucose was 120mg/dl.

On the 50th day: A few microaneurysms, which were observed previously disappeared completely by an ophthalmoscopic examination. Blood vessels were quite normal. Glucosuria was negative both in the morning and in the evening. Blood glucose was 80mg/dl.

On the 60th day: Glucosuria was negative in the morning and in the evening. Blood glucose was 99mg/dl.

On the 70th day: Glucosuria was negative in the morning and almost negative in the evening. Blood glucose was 84mg/dl. The nasopharyngeal treatment was interrupted for about 15 days

because of a trip. The patient caught cold during this interruption.

On the 90th day Severe abrasive pain when $ZnCl_2$ solution was applied in nasopharynx. Slight bleeding Glucosuria was positive in the morning and almost negative in the evening Blood glucose was 112mg/dl.

On the 110th day Glucosuria was negative in the morning and almost negative in the evening Blood glucose was 83mg/dl.

The patient is still under treatment

Case No 29 (Fig 75)

K.K. A 73 year old male with diabetes.

Chief complaints General fatigue furuncle of the head and visual disorders.

Diagnosis Diabetes, diabetic retinopathy (Scott II) aphthous stomatitis (habitual) alveolar pyorrhea and hypertension.

History of diseases The patient had total exhaustion since 10 years before and furuncles were easily formed on the head. Around that time glucosuria was found, which could not be controlled thoroughly in spite of insulin administration and glucosuria never disappeared.

Tests When a glucose tolerance test (50 g glucose) was conducted before starting the nasopharyngeal treatment blood glucose followed the dotted line in Fig 75 and glucosuria was also positive. Blood pressure was 208–94 Bleeding in the retina was observed by an ophthalmoscopic examination and several arteriolo-aneurysms were observed. Marked abrasive pain and bleeding after stimulation of the nasopharynx were observed. Transformation and desquamation of the epithelial cells and appearance of neutrophiles were observed in the smears. Staphylococcus aureus was found.

Treatment A small amount of Xylocain was added to 1 $ZnCl_2$ solution and applied throughly to the nasopharynx. When this treatment was continued every day for one month, glucosuria disappeared, both fasting blood glucose and a glucose tolerance test were significantly improved (the solid line in Fig 75) Blood pressure decreased to 158–80 (refer to the paragraph of blood pressure) and aphtha disappeared also (refer to the paragraph of aphtha) Bleeding in the retina could not be seen thereafter

In the observation for the next 2 years, glucosuria was found two times when the patient caught cold, however it disappeared about one week be the nasopharyngeal treatment. Drugs for diabetes, such as insulin, are not administered now

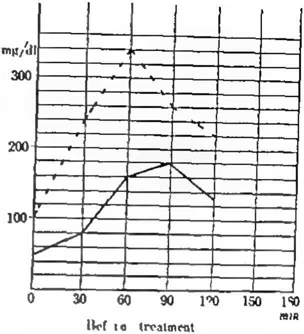

Fig. 75. Case No. 29 (K.K. 73 Y ♂) Glucose (50 g) tolerance test.

About 30 patients with diabetes were treated only by the local nasopharyngeal treatment by now In most of them blood glucose returned to the normal value or came close to it glucosuria disappeared and various symptoms, which accompanied diabetes, also disappeared. Fig 76 showed glucose tolerance tests of 9 patients, to whom 50g of glucose were administered before and after the nasopharyngeal treatment. Except for one patient (I K. 35 year-old male) blood glucose became normal after the treatment (solid lines) and glucosuria disappeared Even in the patient who took a serious turn progress thereafter was favorable and glucosuria was reported to have disappeared As shown in Fig 77 (2) fasting blood glucose decreased after 2 months.

Fig 77 showed changes of fasting blood glucose by the nasopharyngeal treatment As blood glucose during hunger was reported as 60 100 mg dl these values shown in Fig 76 could not be called normal Judging from the disappearance of glucosuria however it could not be denied that the nasopharyngeal treatment was fairly effective It was interesting to know that by the nasopharyngeal treatment glucosuria disappeared and thirst polyphagia emaciation and exhaustion disappeared in most patients.

Besides changes in the pancreas, changes in the blood vessels a

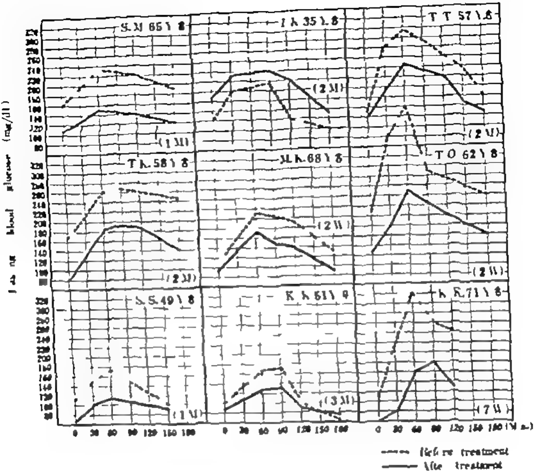

Fig. 76. Diabetes and nasopharyngeal treatment.

condition of diabetes. The changes in the blood vessels are the so-called Kimmelstiel-Wilson's symptom and are the changes in small blood vessels such as those of the kidneys, which the author has never studied. In the eyeground vessels, small aneurysms are often found, which cause bleeding of the eyeground when ruptured. These changes in the blood vessels caused by diabetes are said to be difficult to cure and bleeding of the eyeground might result in blindness after several relapses. It was interesting however that in both 2 patients with bleeding of the eyeground, no bleeding was observed after starting the nasopharyngeal treatment and also in another case with aneurysma, it was found to have completely disappeared after 2 months.

Though the nasopharyngeal treatment was conducted on the patients with Brittle type diabetes, normalization of blood and urinary glucose was not necessarily easy and complete recovery could not be expected. Even in such cases, however it was possible to improve the symptoms remarkably with the nasopharyngeal treatment. Therefore they might have recovered completely if the treatment was continued for a longer term. A patient was found to have Brittle type diabetes after falling into a comatose state. In spite of various treatments with insulin, the patient lost body weight, had thirst and hypoglycemic fits repeatedly. By starting the nasopharyngeal treatment, however his diabetic state was controlled and the amount of insulin could be reduced significantly compared to that used before the nasopharyngeal treatment though

because of a trip The patient caught cold during this interruption

On the 90th day Severe abrasive pain when $ZnCl_2$ solution was applied in nasopharynx. Slight bleeding Glucosuria was positive in the morning and almost negative in the evening Blood glucose was 112mg/dl.

On the 110th day Glucosuria was negative in the morning and almost negative in the evening Blood glucose was 83mg/dl.

The patient is still under treatment.

Case No. 29 (Fig 75)

K.K. A 73 year old male with diabetes.

Chief complaints General fatigue, furuncle of the head and visual disorders.

Diagnosis Diabetes, diabetic retinopathy (Scott II) aphthous stomatitis (habitual) alveolar pyorrhea and hypertension.

History of diseases The patient had total exhaustion since 10 years before and furuncles were easily formed on the head. Around that time glucosuria was found, which could not be controlled thoroughly in spite of insulin administration, and glucosuria never disappeared.

Tests When a glucose tolerance test (50 g glucose) was conducted before starting the nasopharyngeal treatment, blood glucose followed the dotted line in Fig 75 and glucosuria was also positive. Besides changes in the pancreas changes in the blood vessels are observed as an important

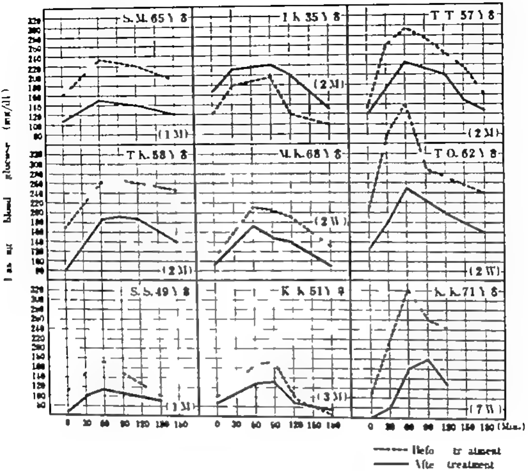

Fig. 78. Diabetes and nasopharyngeal treatment.

condition of diabetes. The changes in the blood vessels are the so-called Kimmelstiel-Wilson symptom and are the changes in small blood vessels such as those of the kidneys, which the author has never studied. In the eyeground vessels, small aneurysms are often found, which cause bleeding of the eyeground when ruptured. These changes in the blood vessels caused by diabetes are said to be difficult to cure and bleeding of the eyeground might result in blindness after several relapses. It was interesting however that in both 2 patients with bleeding of the eyeground, no bleeding was observed after starting the nasopharyngeal treatment and also in another case with aneurysma, it was found to have completely disappeared after 2 months.

Though the nasopharyngeal treatment was conducted on the patients with Brittle type diabetes, normalization of blood and urinary glucose was not necessarily easy and complete recovery could not be expected. Even in such cases, however, it was possible to improve the symptoms remarkably with the nasopharyngeal treatment. Therefore they might have recovered completely if the treatment was continued for a longer term. A patient was found to have Brittle type diabetes after falling into a comatose state. In spite of various treatments with insulin, the patient lost body weight, had thirst and hypoglycemic fits repeatedly. By starting the nasopharyngeal treatment, however, his diabetic state was controlled and the amount of insulin could be reduced significantly compared to that used before the nasopharyngeal treatment though

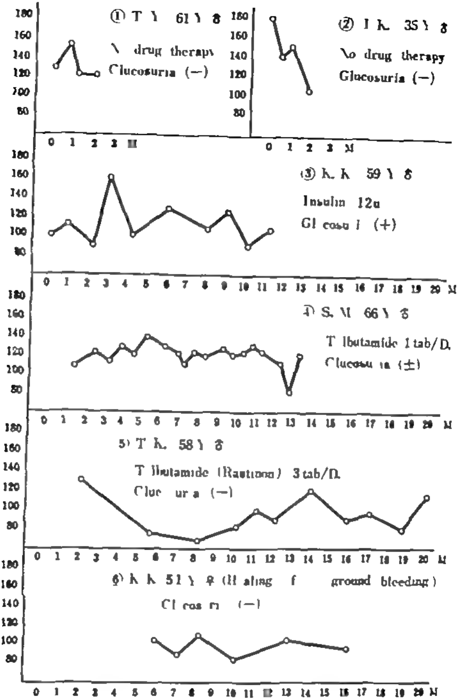

Fig. 77 Course of fasting blood glucose.

insulin administration itself could not be stopped. The patient was working so busily after leaving the hospital that neither the treatment nor the tests could be continued. When asked on the phone 2 years after his leaving the hospital he said that he was working well. It was interesting that the patient always had abnormal feeling in the nasopharynx before he became conscious of symptoms of aggravation of diabetes and he complained of it to a doctor but the doctor never took it seriously. This is a case in which a patient became conscious of the relation between diabetes and nasopharyngitis.

The idea to improve or cure diabetes by the nasopharyngeal treatment is not based on theoretical inference. It is rather based on the experience that diabetes combines with rheumatism and hypertension, and when the nasopharyngeal treatment is conducted for these diseases, diabetes is also improved.

The causes of diabetes are not yet known.

Pregnancy heredity and inflammation are given as proximate causes, but none of them are certain. For example, the relation between inflammation and diabetes is such that diabetes is worsened or started with an attack of acute inflammation.

Most of the patients with diabetes has significant nasopharyngitis. Nasopharyngitis progresses by repeating acute inflammation. Therefore it is possible to look for causes of diabetes in the category of utoimmune diseases resulting from nasopharyngitis. For the a toimmune diseases, however discovery of an autoantibody is necessary as a matter of course.

There is a thought that diabetes may be an uotoimmune disease. Though autoantibody for diabetes has not yet been found, the above supposition is based on the following facts. Namely (1) diabetes is often comlpined w th pernicious anemia, which is an utoimmune disease (2) thyroid antibody is often found in patients with juvenile diabetes (2 patients w th Hashimoto s Disease, one of the autoimmune diseases of the thyroid) were cured by the nasopharyngeal treatment, (3) fluorescent γ-globulin and infiltration of lymphocytes are often observed in pancreatic specimens of patients w th diabetes. Anyway it is certain that diabetes is improved remarkably by the nasopharyngeal treatment. It is not clear yet whether the mechanism of its crisis is due to an autoimmune disease or continuous extrinsic stimulation of the hypothalamus, such as CRF on adrenal and TRF on thyroid, causes dysfunction of Langerhans islands.

2) Thyroidis

Nephritis is said to be a focal infectious disease of parenchymatous organs or n autoimmune disease. Nephritis often responds to nasopharyngeal treatment like rheumatism. Some kinds of thyroidis are also thought to be diseases of autoimmunization and autoantibodies or fluorescent substances are demonstrated. The following are cases which were diagnosed as ha ing the so-called Hashimot Disease and were cured relatively fast by nasopharyngeal treatment. (As the thor had only cases, t is doubtful whether these cases healed by the nasopharyngeal treatment had any uni ersal ability. However the fact could not be denied.)

Case No. 30

K.S., 55 year old male with hypothyroism.

Chief complaints: Edema of the neck.

History: Since few months before, the patient started to feel the collar of his shirt ery tight and he visited the hospital with suspicion of *laryngeal* tumor. Edema was found mainly in the anterior jugulum and was also found in the face, nape, *the back of the hand*, and the *instep* of the foot. One eyelid was swollen. H was unable to speak distinctly. Nephritis could be denied as urinary test was normal. The skin was dull and dry. His complexion was yellowish and did not look well. (No abnormalities were found in liver function and bile excretion.) Swelling of the skin was not so bad as to make hollows. The patient had lost his appetite recently. His movements became slow and he acted passively in everything. Blood pressure was 94-80.

Condition: The laryngeal mucosa was slightly flared. Otorhinological condition was missing. Edema of the anterior jugulum was suggestive of myxedema of the thyroid.

Urinary condition was normal (Protein (−) glucose (−)) cardiac hypertrophy was found by X-ray *photo and slight block was found in ECG* (ST was high). No abnormalities were observed in other organs.

B.M.R. (Basal metabolic rate):		−22%
Thyroid hormone test	20.4%	
Adrenal hormone test	17KS 34 mg/day	
	17 OHCS 22%	

From the scintigram it was found that the picture of the thyroid was faint and scattered, and incorporation was diffusely impaired throughout the organ.

Diagnosis: Chronic thyroiditis.

Treatment: 30 mg of thyroid powder was administered at internal medicine, but the patient decided to undergo the nasopharyngeal treatment instead of taking the drug. At the beginning he complained of severe pain caused by the local nasopharyngeal *treatment* and bleeding was observed after pplication of 1 $ZnCl_2$ solution. In spite of that he felt better after the treatment, and thereafter the nasopharyngeal treatment was continued daily for one month.

(1) Basal metabolic rate after 1 month was 1%.
(2) Cardiac hypertrophy was improved significantly and became normal in X-ray photos.
(3) However no change was observed in ECG and the block was still observed.
(4) Blood pressure was 110/80.
(5) Swelling of the neck disappeared.

Though the patient stopped uniting the hospital for certain reasons, he was fine after 6 months. An important point in this case was that BMR,

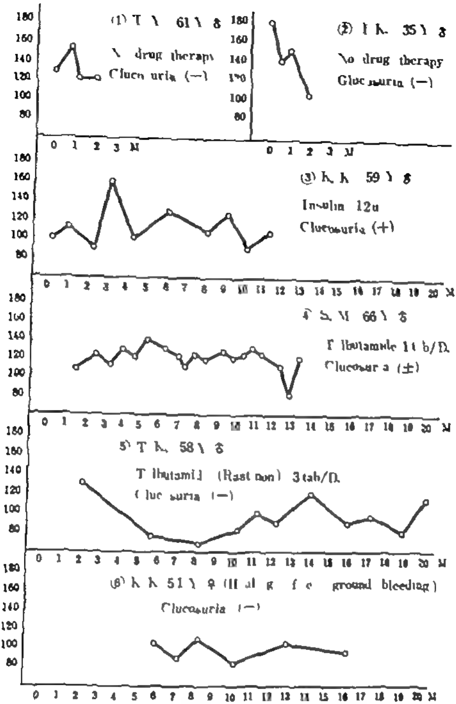

Fig 77 Course of fasting blood glucose.

insulin administration itself could not be stopped. The patient was working so busily after leaving the hospital that neither the treatment nor the tests could be continued. When asked on the phone 2 years after his leaving the hospital he said that he was working well. It was interesting that the patient always had abnormal feeling in the nasopharynx before he became conscious of symptoms of aggravation of diabetes and he complained of it to a doctor but the doctor never took it seriously. This is a case in which a patient became conscious of the relation between diabetes and nasopharyngitis.

The idea to improve or cure diabetes by the nasopharyngeal treatment is not based on theoretical inference. It is rather based on the experience that diabetes combines with rheumatism and hypertension and when the nasopharyngeal treatment is conducted for these diseases, diabetes is also improved.

The causes of diabetes are not yet known.

Pregnancy heredity and inflammation are given as proximate causes, but none of them are certain. For example, the relation between inflammation and diabetes is such that diabetes is worsened or started with an attack of acute inflammation.

Most of the patients with diabetes have significant nasopharyngitis. Nasopharyngitis progresses by repeating acute inflammation. Therefore it is possible to look for causes of diabetes in the category of autoimmune diseases resulting from nasopharyngitis. For the autoimmune diseases, however discovery of an autoantibody is necessary as a matter of course.

There is a thought that diabetes may be an autoimmune disease. Though autoantibody for diabetes has not yet been found, the above supposition is based on the following facts. Namely (1) diabetes is often combined with pernicious anemia, which is an autoimmune disease (2) thyroid antibody is often found in patients with juvenile diabetes (2 patients with Hashimoto's Disease one of the autoimmune diseases of the thyroid) were cured by the nasopharyngeal treatment, (3) fluorescent γ-globulin and infiltration of lymphocytes are often observed in pancreatic specimens of patients with diabetes. Anyway it is certain that diabetes is improved remarkably by the nasopharyngeal treatment. It is not clear yet whether the mechanism of its cause is due to an autoimmune disease or continuous extrinsic stimulation of the hypothalamus, such as CRF on adrenal and TRF on thyroid, causes dysfunction of Langerhans islands.

2) Thyroids

Nephritis is said to be a focal infectious disease of parenchymatous organs or an autoimmune disease. Nephritis often responds to nasopharyngeal treatment like rheumatism. Some kinds of thyroids are also thought to be diseases of autoimmunization and autoantibodies or fluorescent substances are demonstrated. The following are cases which were diagnosed as having the so-called Hashimoto's Disease and were cured relatively fast by nasopharyngeal treatment. (As the author had only 2 cases, it is doubtful whether these cases healed by the nasopharyngeal treatment had any universal validity. However the fact could not be denied.)

Case No. 30

K.S., 55 year old male with hypothyroidism.

Chief complaint Edema of the neck.

History Since a few months before, the patient started to feel the collar of his shirt very tight and he visited the hospital with suspicion of laryngeal tumor. Edema was found mainly in the anterior jugulum and was also found in the face, nape, the back of the hand, and the instep of the foot. One eyelid was swollen. He was unable to speak distinctly. Nephritis could be denied as urinary test was normal. The skin was dull and dry. His complexion was yellowish and did not look well. (No abnormalities were found in liver function and bile excretion.) Swelling of the skin was not so bad as to make hollows. The patient had lost his appetite recently. His movements became slow and he acted passively in everything. Blood pressure was 94-80.

Condition The laryngeal mucosa was slightly flared. Otorhinological condition was missing. Edema of the anterior jugulum was suggestive of myxedema of the thyroid.

Urinary condition was normal (Protein (−) glucose (−)) cardiac hypertrophy was found by X-ray photo and slight block was found in ECG (ST was high). No abnormalities were observed in other organs.

B.M.R. (Basal metabolic rate) −22%
Thyroid hormone test 20.4%
Adrenal hormone test: 17KS 3.4 mg/day
17 OHCS 22%

From the scintigram it was found that the picture of the thyroid was faint and scattered, and incorporation was diffusely impaired throughout the organ.

Diagnosis Chronic thyroiditis.

Treatment 30 mg of thyroid powder was administered as internal medicine, but the patient decided to undergo the nasopharyngeal treatment instead of taking the drug. At the beginning he complained of severe pain caused by the local nasopharyngeal treatment and bleeding was observed after application of 1% $ZnCl_2$ solution. *In spite of that he felt better after the* treatment, and thereafter the nasopharyngeal treatment was continued daily for one month.

(1) Basal metabolic rate after 1 month was 1%.
(2) Cardiac hypertrophy was improved significantly and became normal in X-ray photos.
(3) However no change was observed in ECG and the block was still observed.
(4) Blood pressure was 110/80.
(5) Swelling of the neck disappeared.

Though the patient stopped visiting the hospital for certain reasons, he was fine after 6 months. An important point in this case was that BMR,

which was −11 at the beginning, was improved to +1 after 1 month of the nasopharyngeal treatment. This was a case of the so-called Hashimoto's Disease, dysfunction of the thyroid, which was thought to be an autoimmune disease of the thyroid. Though it is said that there is no special treatment for this disease other than administration of hormones, it was improved significantly by the nasopharyngeal treatment. The author found another such case.

The author conducted the nasopharyngeal treatment on 5 patients with hyperfunction of the thyroid and succeeded in normalizing the basal metabolic rate, increasing the body weight and eliminating of the thyroid symptoms. Swelling of the thyroid however did not disappear in these cases.

3) Slight Fever

Tonsillopathy is often given as a cause of pyrexia of unknown origins. When pyrexia lasts in spite of tonsillectomy nasopharyngitis is often found as a cause for that. When smears of nasopharynx of these patients are tested directly without being too particular about tonsillitis (regardless of the presence of tonsillitis) severe inflammation is observed (bleeding after abrasion and the presence of erosion are found) and pyrexia of unknown origins is controlled in many cases by the local nasopharyngeal treatment. This is often observed in the case when pyrexia lasts after catching cold (It can be *thought as acute nasopharyngitis.*)

Case No. 31

E.N 11 year old girl with slight fever

History of diseases 3 months before visiting the hospital the patient complained of headache and left school earlier than usual. Her body temperature was 37.3 C and she was administered an antibiotic by a specialist in pediatrics. Fever however was not alleviated. Then the patient was sent to an otorhinologist, who told that she was in good condition after examining her throat. (This is an important point!) The body temperature still stayed around 37.5 C after the laryngeal examination. About 2 months before visiting our hospital the patient was sent to the internal medicine dept. of university hospital when she was told she was normal after a total examination, such as urinary tests, blood tests X ray photos, etc The patient was still feverish, complained of headache and exhaustion lost her will to study and missed school

Otorhinological condition No changes were observed in general otorhinological tests. Both palate and tonsils were normal. However the patient complained of severe pain after abrasion of the nasopharynx with a cotton swab and a large quantity of blood came out after the abrasion. Inflammation was observed clearly in the smeared specimens, which suggested the presence of erosion in the nasopharynx. (In children younger than this age the conditions mentioned above were often observed after abrasion of nasopharynx.)

Clinical course Treatments other than application of 1 $ZnCl_2$ solution (with a small amount of Xylocain added) every day to the nasopharynx were rejected. Antifebriles were also prohibited to see the effect of the nasopharyngeal treatment on febricula. After starting the nasopharyngeal treatment, the patient progressed favorably a normal temperature was obtained 3 days after starting the treatment and the temperature never went up. On the 20th day however the patient caught cold, the body temperature went up to 37.3 °C, and abrasive pain and bleeding after abrasion of the nasopharynx came back again (The author thinks that a cold is a symptom of the autonomic nervous system, which comes out after acute nasopharyngitis. In fact some patients complained of catching cold immediately after application of a medical solution to the nasopharynx.) This condition disappeared by conducting the nasopharyngeal treatment for a few days, and the body temperature returned to its normal value. As the body temperature stayed normal, the treatment was stopped after 3 months. The patient was observed for 1 year after that and she never had an attack of fever during this period.

Slight fever is encountered in children very often. According to a survey those whose axillary temperature exceeded 37.1 C were 26, 47.2 and 60 in the morning for test periods of 5 10 and 15 minutes respectively and 41.0 64.4 and 80.2 in the afternoon. Though it was concluded that febricula was their normal physiological condition, it would be difficult to conclude that so many school children (about 0% of them) had nasopharyngitis, an abnormal condition. When the nasopharyngeal treatment was conducted on some children, who were chosen arbitrarily from such school children with febricula, their body temperature returned to normal and they became extremely energetic.

Habitual pyrexia of school children or essential pyrexia) is not so simple as that mentioned above It is related to diseases, such as rheumatic fever (high ASL-O value) subsepsis allergica, habitual cold, bronchial asthma, habitual purpura and hemopathy characterized and treated according to each disease On the contrary the author thinks that the diseases, which should belong to the same category appeared with various faces.

The reason for this is that all of these diseases are combined with nasopharyngitis, and they are often cured by the local treatment of the nasopharynx.

4) Epistaxis

The nasopharyngeal treatment is very effective on epistaxis in some cases. As local hemostasia was thought to be most important in the past, a tampon and cauterization were used. Ligation of A. sphenopalatina and Aa. ethmoidales was also conducted locally.

The author however obtained successful results by application of 1% $ZnCl_2$ solution to the nasopharynx of the patients with epistaxis. The idea was obtained from finding that in habitual epistaxis of children (for example, rhinorrhagia caused by the adenoids) severe inflammation was often observed in the nasopharynx and by treating the inflammation locally (application of 1% $ZnCl_2$ solution to the nasopharynx) the habitual epistaxis was cured.

The reason is probably that inflammation in the nasopharynx, which extended to Locus Kiesselbachi and other nasal mucous membrane through rhinal ground and nasal mucous membrane, became susceptible to bleeding. Fortunately the nasopharyngeal treatment was extremely effective on epistaxis and hemostasia was obtained by only one treatment as shown in the example below. Though it is doubtful that nasopharyngitis is a cause of the inflammation when such quick hemostasia is obtained, nasopharyngitis and nasal vestibulitis could be causes of habitual epistaxis of school children.

There is no need to think that inflammation of nasal vestibule is extended from the nasopharynx. In the transitional zone of Apertula piriformis to the mucous membrane there was inflammation severer than that found in the nasopharynx in many cases. This is probably because bigger molecules of dust in the air which come and go by respiration, adhere to the mucous membrane around the nasal vestibule and nostrils and cause inflammation there. Judging from this it should be said that L. Kiesselbachi is simply apt to cause inflammation and bleeding rather than that L. Kiesselbachi is apt to bleed because of its being rich in blood vessels.

Case No. 2

8 year old boy with habitual epistaxis.

History of disease Since he was 6 years old, he was susceptible to epistaxis. In the beginning bleeding could be stopped relatively easily by plugging the nasal cavity with cotton and cooling the bridge of the nose at home. Epistaxis became severer and severer and the patient visited an otorhinologist. There was no abnormal component in the blood, no prolongation of bleeding time and no special causes of bleeding such as tumor. However the patient was found to have rhinitis anterior sicca. The bleeding was said to be from L. Kiesselbachii (Little's area) which was cauterized, and a styptic was administered.

Condition There was inflammation in the nasal vestibule. Especially the mucous membrane of L. Kiesselbachii was cyanotic, blood vessels were cut here and there and some bleeding was observed.

Treatment A tampon was rejected and 1% $ZnCl_2$ solution was applied to the nasopharynx. The patient complained of severe pain and large amount of bleeding was observed from nasopharynx. (There was no need to worry about the bleeding as it was thought to be superficial.) The patient was diagnosed as having severe nasopharyngitis by testing smears.

From the day of starting the nasopharyngeal treatment, epistaxis stopped. After 1 month of daily nasopharyngeal treatment, the treatment was stopped. The patient was observed for 2 years after that without any bleeding.

When the nasopharynx of patients with habitual epistaxis of unknown origins was tested, severe inflammation (erosion) was found and bleeding was observed on application of $ZnCl_2$ solution in many cases. The bleeding was stopped by the nasopharyngeal treatment. It was demonstrated that fibrinolysis was accelerated by the nasopharyngeal stimulation and the acceleration was significant when the patient had acute nasopharyngitis. It was also observed that the accelerated fibrinolysis was restored to its normal state by the nasopharyngeal treatment. Though this might not be all that activated the mechanism of hemostasis by the nasopharyngeal treatment, this possibly played a part. The following is a case of more serious adult epistaxis.

Case No. 33

A.T. 18 year old male with epistaxis (thrombocytopathia).

History of disease Since he was 3 years old, the patient had nose bleeding about 2 times a year. His younger brother had the same trouble.

When he got hurt, it was difficult to stop the bleeding Frequency and quantity of bleeding increased gradually When he was in the 3rd grade of elementary school (9 years old) the patient was hospitalized because of severe nose bleed and was given a transfusion of 100ml of blood every day Though the epistaxis stopped in one day he stayed at the hospital for 3 to 4 months because of anemia. When he was in the 5th grade of elementary school (11 years old) patient was hospitalized again for epistaxis.

After that he went to the hospital 1 to 2 times a year because of epistaxis. Since he was in the 1st grade of junior high school (13 years old) the patient experienced bleeding from the gingiva occasionally which stopped spontaneously

On July 20th of 1970 he had anorexia and pain at hypochondrium and was diagnosed to have duodenal ulcer His chief complaints were nasal bleeding and hypochondrial pain and he was taken to internal medicine.

Condition Blood pressure was 176–80 Bleeding time was more than 20 minutes. Coagulation time was 5 minutes. Rumpel Leede was (卌) Blood platelets were basophilic and large. Hb 13 1 RBC 440×10⁴ Ht 42 Ret 4 Pl 1 3 WBC 5 600

CRP (−) ASLO 50 WR (−) LE cell (−) Thoracic XP normal.

Bleeding from the nose increased 5 days after hospitalization, and Ht, which was 42 when he was hosp talized decreased to 25 Hemostasis could not be obtained in spite of administering various drugs. An otorhinologist on duty was asked to visit the patient and bleeding was found to occur from the free end of the inferior turbinate body and L. Kiesselbachii. An intranasal tampon was used but blood was oozing from the tampon The tampon was changed every day and th bleeding area was cauterized The cauterization however caused bleeding from another place When use of a tampon was stopped bleeding started again and thereafter it could not be stopped

Twenty days after starting the otorhinological treatment 1 $ZnCl_2$ solution was applied to the nasopharynx for trial Though severe pain and bleeding from the nasopharynx were observed after the application of 1 $ZnCl_2$ solution nose bleed stopped on that day A tampon was removed the day after w thout any hemorrhage The nasopharyngeal treatment was continued for about 1 m nth and the patient left the hosp tal after making sure that no mor bleeding occurred.

As the patient never visited our hospital thereafter his present cond tion is not known. It is certain however that the nasopharyngeal treatment was effecti e in this case.

5) Various Cases Cured by Vasodilatation

It was mentioned in the basic chapter that nasopharyngitis stimulated the peripheral vasomotor nerve. It was not clear however by what kind of mechanism it occurred clinically In the example shown in the preceeding paragraph it was simply a clinical experience that the nasopharyngeal irritation and the treatment of nasopharyngitis were extremely effective on hemostasis of epistaxis and the reason could not be explained.

It could be thought however that the nasopharyngeal treatment affected the opening and closing of the vascular lumen. Therefore the author tried the nasopharyngeal treatment on a few diseases, which were caused by dysfunction of the vasomotor nerve. Though there were only a few cases the author thought that this was a hopeful experiment and wanted to study more of these cases.

The 1st case was a 58 year old woman with thromboarteritis obliterans. Her right leg below the talocrural articulation was all black because of necrosis. The right femoral artery could hardly be palpated the right pelvic limb was discolored as far as the upper femur and the patient was inoperable. When the nasopharyngeal treatment was started, circulation of the blood was rapidly recovered and amputation of the foot became possible after 1 week of the nasopharyngeal treatment.

The 2nd case was a 63 year old male with a fit of acute cerebral embolism. The patient was hospitalized the day after the fit. He had total paralysis f the right arm and foot and right facial nerve. The nasopharyngeal treatment was started i mmediately after hospitalization. From the day of starting the treatment, the patient showed signs of recovery After 10 days he could t up in bed by himself and after 2 weeks he could walk with the help of cane. In th 4th week he did not need the cane any more and in the 2nd month grasping power of both hands became equal.

This patient might have recovered spontaneously but, this was a case of complet recovery of total hem plegia in 2 months using the nasophary geal treatment. Those cases, which a e called cerebral thrombosis or embolism, are of not thrombotic but spastic nature according to my opinion. When the angiospasm lasts for a long period there arises thrombus or neuryan

The 3rd case was a 32 year old woman with possible Raynaud Disease When she was exposed to cold ai her hands became pale or cyanotic. The patient visited various doctors for 10 years but was told that her disease was incurable. Thougl the symptoms were improved rapidly after tart ng the nasophary n-

geal treatment, it was not cured completely. It was interesting to observe that her hands and fingers, which were cyanotic, became rosy immediately after application of ..% $ZnCl_2$ solution in nasopharynx.

6) Cases which were Thought to Have Dysfunction of the Central Nervous System

The patient mentioned in the paragraph about dysfunction of the autonomic nervous system was nervous and was not satisfied with her daily life. However she became cheerful after the nasopharyngeal treatment. A similar change was often observed in cases of O.D. As mentioned in the paragraph about the autonomic nervous system, depression was thought to arise for a reason similar to that of masked depression. In the patient with masked depression, depression appears when he has incurable rheumatism or hypertension. Nasopharyngitis could be a cause of rheumatism or hypertension as mentioned before, and therefore nasopharyngitis might be a cause of such depression. If so there might be a kind of depression induced by nasopharyngitis among the depressions which are not combined with rheumatism or hypertension. As the nasopharyngeal stimulation caused contraction of the peripheral blood vessels, it also might affect cerebral blood vessels. When changes in the arteries of the eyeground were tested by the nasopharyngeal stimulation, changes similar to those in digital blood vessels were observed. It could not be said decisively as the author had only a few cases. Many patients felt sleepy immediately after the nasopharyngeal treatment and became clearheaded after a while, which might be a proof that nasopharyngitis affected cerebral blood flow. The following is a case of depression in which nasopharyngeal treatment was conducted.

Case No. 4

K. O. 16-year-old boy with depression

The patient had severe headache since 4 years before and was diagnosed as having vascular headache at the cerebral surgery department. Though he was treated for 1 year the headache was not improved. He became enervated and slow in reaction. He was examined again at the cerebral surgery department and said to be not pathologic. He was sent to the psychiatric department and diagnosed as having depression. After he was hospitalized and administered various drugs, he suffered from gastrointestinal disorders and anorexia, which became worse and worse, and got a mask-like face. Though he used to be cheerful and laugh a lot, recently he did not laugh at all.

He was said to have nasal allergy in his childhood. He had a stuffy nose since that time. A member of his family thought that the present symptoms might be caused by the nasal allergy in his childhood, and took him to our hospital. He had a mask-like face without any emotional expression, did not answer our questions and did not laugh at all.

The inferior turbinate was enlarged, which showed the presence of severe hypertrophic rhinitis. Nasopharyngeal treatment (refer to the paragraph on nasal allergy) was decided on. When the nasopharynx was abrased, severe pain and bleeding of a large quantity were observed. As severe inflammation was observed also in the smeared specimens, it was diagnosed as nasopharyngitis and the treatment was started.

Treatment: 1% $ZnCl_2$ solution was applied to the nasopharyngeal mucous membrane every day. Drugs prescribed at the psychiatric department were rejected. Though significant abrasal pain and hemorrhage were observed at the beginning, bleeding decreased markedly after 5 days. After 2 weeks, abrasive pain was reduced and no more bleeding was observed. Headache was also improved remarkably. One month after starting the treatment, headache disappeared, the stuffy nose was also improved and hypertrophy of the inferior turbinate body disappeared also. Since then the patient started to talk little by little and laugh from time to time. His family was so happy about his progress. He left the psychiatric department and became an out-patient. He became cheerful after 2 months and spoke cheerfully about his attending school from the next semester.

It is not known whether this was genuine depression or not. According to a psychiatrist, there are such cases among genuine depression cases, and classification can be made only by watching their progress. If so, it seemed but worth studying whether those whose condition at the beginning was the same, but whose progress was unfavorable, became genuinely depressive.

7) Nocturnal Enuresis

It was discovered accidentally that the nasopharyngeal treatment was effective on nocturnal enuresis, and there was no theoretical relation between them. The first case was a boy with infantile asthma, on whom the nasopharyngeal treatment was conducted and nocturnal enuresis disappeared 3 days after starting the treatment. After that 6 cases with enuresis

When he got hurt, it was difficult to stop the bleeding Frequency and quantity of bleeding increased gradually When he was in the 3rd grade of elementary school (9 years old) the patient was hospitalized because of severe nose bleed and was given a transfusion of 100ml of blood every day Though the epistaxis stopped in one day he stayed at the hospital for 3 to 4 months because of anemia. When he was in the 5th grade of elementary school (11 years old) patient was hospitalized again for epistaxis.

After that he went to the hospital 1 to times a year because of epistaxis. Since he was in the 1st grade of junior high school (13 years old) the patient experienced bleeding from the gingiva occasionally which stopped spontaneously

On July 20th of 1970 he had anorexia and pain at hypochondrium and was diagnosed to have duodenal ulcer His chief complaints were nasal bleeding and hypochondrial pain and he was taken to internal medicine.

Condition Blood pressure was 126–80 Bleeding time was more than 20 minutes. Coagulation time was 5 minutes. Rumpel Leede was (†††) Blood platelets were basophilic and large. Hb 13 1 RBC 440×10^4 Ht 42 Ret 4 PI 1.3 WBC 5 600

CRP (−) ASLO 50 WR (−) LE cell (−) Thoracic XP normal

Bleeding from the nose increased 5 days after hospitalization and Ht, which was 42 when he was hospitalized, decreased to 25 Hemostasis could not be obtained in spite of administering various drugs. An otorhinologist on duty was asked to visit the patient and bleeding was found to occur from the free end of the inferior turbinate body and L. Kiesselbachii An intranasal tampon was used but blood was oozing from the tampon. The tampon was changed every day and the bleeding area was cauterized. The cauterization, however caused bleeding from another place. When use of a tampon was stopped, bleeding started again and thereafter it could not be stopped.

Twenty days after tarting the otorhinological treatment, 1 $ZnCl_2$ solution was applied to the nasopharynx for trial Though severe pain and bleeding from the nasopharynx were observed after the application of 1 $ZnCl_2$ solution nose bleed stopped on that day A tampon was removed the day after w thout any hemorrhage The nasopharyngeal treatment was continued for about 1 month and the patient left the hospital after making sure that no more bleeding occurred.

As the patient never isited our hosp tal there after his present condition is not known. It is certain, however that the nasopharyngeal treatment was effect e in this case

5) Various Cases Cured by Vasodilatation

It was mentioned in the basic chapter that nasopharyngitis stimulated the peripheral vasomotor nerve. It was not clear however by what kind of mechanism it occurred clinically In the example shown in the preceeding paragraph it was simply a clinical experience that the nasopharyngeal irritation and the treatment of nasopharyngitis were extremely effective on hemostasis of epistaxis, and the reason could not be explained.

It could be thought, however that the nasopharyngeal treatment affected the opening and closing of the vascular lumen Therefore the author tried the nasopharyngeal treatment on a few diseases, which were caused by dysfunction of the vasomotor nerve. Though there were only a few cases the author thought that this was a hopeful experiment and wanted to study more of these cases.

The 1st case was a 58 year old woman with thromboarteritis obliterans. Her right leg below the talocrural articulation was all black because of necrosis. The right femoral artery could hardly be palpated, the right pel ic limb was discolored as far as the upper femur and the patient was inoperable. When the nasopharyngeal treatment was started, circulation of the blood was rapidly recovered and amputation of the foot became possible after 1 week of the nasopharyngeal treatment.

The 2nd case was a 63 year old male with a fit of acute cerebral embolism. The patient was hospitalized the day after the fit. He had total paralysis of the right arm and foot and right facial nerve. The nasopharyngeal treatment was tarted immediately after hospitalization. From the day of starting the treatment, the patient showed signs of recovery After 10 days he could sit up in bed by himself and after 2 weeks he could walk w th the help of a cane. In the 4th week he did not need th cane anymore and in the 2nd month grasping power of both hands became equal

This patient might ha e reco ered spontaneously but, this was a case of complete recovery of total hemiplegia in 2 months using the nasopharyngeal treatment Those cases, which are called cerebral thrombosis or embolism, are of not thrombotic but spastic nature according to my opinion When the angiospasm lasts for a long period, there arises a thrombus or neurysm.

The 3rd case was a 32 year old woman w th possibl Raynaud Disease. When she was exposed to cold air her hands became pale or cyanotic. The patient visited arious doctors for 10 years but was told that her disease was incurable. Though the ymptoms were improved rapidly after starting the nasopharyn

gal treatment, it was not cured completely. It was interesting to observe that her hands and fingers, which were cyanotic, became rosy immediately after application of 1% $ZnCl_2$ solution in nasopharynx.

6) Cases which were Thought to Have Dysfunction of the Central Nervous System

The patient mentioned in the paragraph about dysfunction of the autonomic nervous system was nervous and was not satisfied with her daily life. However she became cheerful after the nasopharyngeal treatment. A similar change was often observed in cases of O.D. As mentioned in the paragraph about the autonomic nervous system, depression was thought to arise for a reason similar to that of masked depression. In the patient with masked depression, depression appears when he has incurable rheumatism or hypertension. It is not known whether this was genuine depression or not. According to a psychiatrist, there are such cases among genuine depression cases, and classification can be made only by watching their progress. If so, it seemed but worth studying whether those whose condition at the beginning was the same, but whose progress was unfavorable, became genuinely depressive.

7) Nocturnal Enuresis

It was discovered accidentally that the nasopharyngeal treatment was effective on nocturnal enuresis, and there was no theoretical relation between them. The first case was a boy with infantile asthma, on whom the nasopharyngeal treatment was conducted and nocturnal enuresis disappeared 3 days after starting the treatment. After that 6 cases with enuresis

When he got hurt, it was difficult to stop the bleeding · Frequency and quantity of bleeding increased gradually When he was in the 3rd grade of elementary school (9 years old) the patient was hospitalized because of severe nose bleed and was given a transfusion of 100ml of blood every day Though the epistaxis stopped in one day he stayed at the hospital for 3 to 4 months because of anemia. When he was in the 5th grade of elementary school (11 years old) patient was hospitalized again for epistaxis.

After that he went to the hospital 1 to 2 times a year because of epistaxis. Since he was in the 1st grade of junior high school (13 years old) the patient experienced bleeding from the gingiva occasionally which stopped spontaneously

On July 20th of 1970 he had anorexia and pain at hypochondrium and was diagnosed to have duodenal ulcer His chief complaints were nasal bleeding and hypochondrial pain and he was taken to internal medicine.

Condition Blood pressure was 126–80 Bleeding time was more than 20 minutes. Coagulation time was 5 minutes. Rumpel Leede was (卄) Blood platelets were basophilic and large. Hb 13 1 RBC 440×10^4 Ht 42 Ret 4 Pl 1.3 WBC 5 600

CRP (−) ASLO 50 WR (−) LE cell (−) Thoracic XP normal

Bleeding from the nose increased 5 days after hospitalization, and Ht, which was 42 when he was hospitalized decreased to 25 · Hemostasis could not be obta ned in sp te of administering various drugs. An otorhinologist on duty was asked to visit the patient and bleeding was found to occur from the free end of the inferior turbinat body and L. Kiesselbachii. An intranasal tampon was used but blood was oozing from the tampon The tampon was changed every day and the bleeding rea was cauterized The cauterization, however caused bleeding from another place When use of a tampon was stopped, bleeding started gain and thereafter t could not be topped

Twenty days after tarting the otorhinological treatment 1 $ZnCl_2$ solut on was appl ed to the nasophary nx for trial Though severe pa n and bleed ng from the nasopharynx w re observed after the pplication of 1 $ZnCl_2$ solution nose bleed stopped on that day A tampon was removed the day after w thout y hemorrhag

The nasopharyngeal tre tment was continued for about 1 month and the patient left the hosp tal after making ure that no mor bleed ng occurred.

As the patient never visited our hospital thereafter his present condition is not known. It is certain, however that the nasopharyngeal treatment was effect in this case

5) Various Cases Cured by Vasodilatation

It was mentioned in the basic chapter that nasopharyngitis stimulated the peripheral vasomotor nerve. It was not clear however by what kind of mechanism it occurred clinically In the example shown in the preceeding paragraph it was simply a clinical experience that the nasopharyngeal irritation and the treatment of nasopharyngitis were extremely effective on hemostasis of epistaxis, and the reason could not be explained

It could be thought however that the nasopharyngeal treatment affected the opening and closing of the vascular lumen Therefore the author tried the nasopharyngeal treatment on a few diseases, which were caused by dysfunction of the vasomotor nerve Though there were only a few cases, the author thought that this was a hopeful experiment and wanted to study more of these cases.

The 1st case was a 58 year old woman with thromboarteritis obliterans. Her right leg below the talsocrural articulation was all black because of necrosis. The right femoral artery could hardly be palpated, the right pelvic limb was discolored as far as the upper femur and the patient was inoperable. When the nasopharyngeal treatment was started, circulation of the blood was rapidly recovered and amputation of the foot became possible after 1 week of the nasopharyngeal treatment

The 2nd case was a 63 year old male w th a fit of acute cerebral embolism. Th patient wa hospitalized the day after the fit. H had total paralysis of the right arm and foot and right facial nerv The nasophary geal treatment was started immediately after hospitalization. From the day of starting the treatment the patient showed signs of recovery After 10 days he could sit up bed by himself and after 2 weeks he could walk w th th help of a cane In the 4th week he did not need th cane a ymore and in the 2nd month graspi g power of both hands became equal

This patient might h recovered spontaneously but this was a case of complet recovery of total hemiplegia in 2 months using the nasopharyngeal treatment. Those cases, which re c lled cerebral thrombosis or embolism, re of not thrombotic but spastic nature according to my opinion When the angiospasm lasts for long period there arises thrombus or neurysm

The 3rd case was a 3_ year old woman w th possible Raynaud s Disease When she was exposed to cold air her hands became pale or cyanotic The pat ent isited various doctors for 10 years but was told that her disease was incurabl Though t y ptoms were improved rapidly after tarting the nasopharyn

Fatigue	30	43	43	43	52
Epistaxis	6	4	15	18	12
Sweating	—	—	—	80	26

by KITAMOTO et al. is thought to be this kind of pain, namely nasopharyngeal pain. Genuine oropharyngeal pain appears mostly as unilateral tonsillar pain, and rarely appears in the median portion.

(3) Headache in case of a common cold can be explained as the pain radiated from the nasopharyngeal wall or the wall of the inferior nasal meatus as shown in the paragraph on headache and nasopharyngitis.

(4) There is a close relationship between nasopharyngitis and pyrexia as mentioned previously in the paragraph on pyrexia.

( ) It was reported previously that so-called nasal allergy was closely related to nasopharyngitis. Nasal symptoms combined with acute nasopharyngitis are thought to be kind of irritating symptoms. The so-called catarrhal rhinitis was demonstrated to be closely related to nasopharyngitis.

(6) Open nasal voice which appears in the first stage of common cold together with an abnormal feeling in the nasopharynx or pharynx. Nasal sounds such as m, n and ŋ twang characteristic [illegible] is thought to be Rhinolalia aperta due to slight paresis of the soft palate.

7 When the nasopharynx of the patients with chronic abnormal feeling of the body was abraded with cotton swab moistened with 1 $ZnCl_2$ solution they complained of severe fatigue immediately after the treatment. In the treatment of nasopharyngitis or in the nasopharyngeal stimulation, the patients were attacked by unusual exhaustion and could not even stand up. This was probably related to exhaustion caused by the common cold.

(8) Some patients complained of catching cold immediately after the nasopharyngeal treatment (application of a drug solution). It was thought that reaction to local stimulation of the nasopharynx appeared locally and totally which was an interesting experimental observation. This feeling of catching cold often disappeared in 2 or 3 hours.

(9) The common cold was cured relatively easily by the nasopharyngeal treatment.

(10) All children who catch cold easily or those who catch cold all the time, ha e severe nasopharyngitis and by continuing local treatment of nasopharyngitis, they rarely catch cold or get by with only a slight cold.

(11) Epistaxis is thought to be related to an acute inflammation of the nasal mucous membrane, which follows nasopharyngitis, and can be cured easily by the nasopharyngeal treatment.

From the above facts, the common cold can be thought of as autonomic neurosis caused by acute nasopharyngitis. In fact prolongation of digital pulse wave contraction time or transition of normal to abnormal type blood pressure was observed after the nasopharyngeal stimulation of patients with colds. Local treatment of the nasopharynx is the most effective for the common cold, and the common cold can be prevented in many cases by continuing the nasopharyngeal treatment.

It was often shown that the common cold or influenza was caused by viral infection, and this fact is not inconsistent with nasopharyngitis. It can be thought that acute nasopharyngitis is

were collected and enuresis was cured in all of them after treating the nasopharynx 3 to 5 times. As the *nasopharyngeal treatment* was continued for 3 to 5 months after enuresis was stopped in these cases, it is not known whether enuresis would have been caused again if the treatment was stopped earlier

8) Pseudomyopia

As it is often said that myopia is due to abnormality of the autonomic nervous system the nasopharyngeal treatment was tried on pseudomyopia in the early stage of myopia Some pseudomyopia progresses to genuine myopia and other cases are cured spontaneously but their distinction between them and only those which become incurable, progress to genuine myopia As one cause of genuine myopia is abnormality of the autonomic nervous system it was not unreasonable to try the nasopharyngeal treatment on it as permanent treatment of abnormality in the autonomic nervous system (Refer to the paragraph on nasopharyngitis and the autonomic nervous system)

When the nasopharyngeal treatment was conducted on children with pseudomyopia the visual power of one child was improved from 0 3 to 0 7 after 2 months The visual power of another child was also improved As the treatment had to be stopped in both cases because of attending school definite results were not known However significant response was observed in 2 cases and this problem has to be studied further

9) Ozostomia (Foetor ex ore)

It was observed in many cases that ozostomia disappeared after the nasopharyngeal treatment. It was probably due to the fact that some of the bacteria which caused nasopharyngitis, had an unpleasant odor and they were removed by the treatment. It was also probable that alveolar pyorrhea aphtha chronic tonsilitis and gastric diseases were improved by the nasopharyngeal treatment and ozostomia was removed secondarily There were actual cases anyhow where an ozostomia was partly removed by the nasopharyngeal treatment

10) Dysosmia

Dysosmia of unknown origins was rarely cured by the nasopharyngeal treatment. In the case over olfactory cleft, dysosmia would be cured with disappearance of inflammation.

11) Common Cold

As studies on influenza made progress and various viruses were discovered the distinction between the common cold and influenza became unclear and a cold was simply concluded to be a viral infection Though it could not be denied that viral infection was a cause of the common cold and influenza there was no explanation for a fundamental question that various symptoms of the so-called common cold were thought due to abnormality of the autonomic nervous system.

When the nasopharynx of a patient with a common cold was observed there existed acute aggravation of nasopharyngitis and this aggravation was improved with recovery from the cold. (On the contrary those in whom acute aggravation of nasopharyngitis was observed did not necessarily have a cold.) It was certain that there was a close relationship between the common cold and acute nasopharyngitis.

Table 69 by KITAMOTO et al (1970) shows general symptoms when influenza was prevalent The relation between nasopharyngitis and symptoms other than cough and sputum shown in this table was mentioned previously in this thesis. Cough and sputum were seen in the case of tracheitis or bronchitis, and most of the patients with acute or chronic tracheitis or bronchitis had severe nasopharyngitis, of which local treatment cured tracheitis in a short term.

In relation between total symptoms of the so-called common cold and nasopharyngitis mentioned above

(1) When the nasopharynx of those with a common cold or influenza was observed, there was always acute aggravation of inflammation.

(2) In the first stage of the common cold, many people complained of abnormal feeling on the dorsal surface of the soft palate (Though this abnormal feeling was often spoken of as an abnormal feeling in the head or throat or as sore throat they did not have much change in oro- and hypopharynx and larynx. When the nasopharynx was examined however severe pain and bleeding were observed and severe inflammation was found in the smears.

(7) When the nasopharynx of the patients with chronic abnormal feeling of the body was brushed with a cotton swab moistened with 1% $ZnCl_2$ solution, they complained of severe fatigue immediately after the treatment. In the treatment of nasopharyngitis or in the nasopharyngeal stimulation, the patients were attacked by unusual exhaustion and could not even stand up. This was probably related to exhaustion caused by the common cold.

(8) Some patients complained of catching cold immediately after the nasopharyngeal treatment (application of a drug solution). It was thought that reaction to local stimulation of the nasopharynx appeared locally and totally, which was an interesting experimental observation. This feeling of catching cold often disappeared in 2 or 3 hours.

(9) The common cold was cured relatively easily by the nasopharyngeal treatment.

(10) All children who catch cold easily or those who catch cold all the time, have severe nasopharyngitis and by continuing local treatment of nasopharyngitis, they rarely catch cold or get by with only a slight cold.

(11) Epistaxis is thought to be related to an acute inflammation of the nasal mucous membrane, which follows nasopharyngitis, and can be cured easily by the nasopharyngeal treatment.

From the above facts, the common cold can be thought of as autonomic neurosis caused by acute nasopharyngitis. In fact prolongation of digital pulse wave contraction time or transition of normal to abnormal type blood pressure was observed after the nasopharyngeal stimulation of patients with colds. Local treatment of the nasopharynx is the most effective for the common cold, and the common cold can be prevented in many cases by continuing the nasopharyngeal treatment.

It was often shown that the common cold or influenza was caused by viral infection, and this fact is not inconsistent with nasopharyngitis. It can be thought that acute nasopharyngitis is

caused by viral infection. It should be further studied, however whether the differences in neurotic characteristics, which accompany the common cold are due to virus. The neurosal symptoms of the common cold can be explained simply by acute nasopharyngitis.

6 Conclusion and Summary

The word "nasopharyngeal treatment" was often used in this thesis. By this word it was meant that 1% $ZnCl_2$ solution was applied thoroughly to the nasopharyngeal wall with the aid of a cotton applicator (nasal and pharyngeal cotton applicator).

All the experiments were conducted using only this simple technique. It was not because this technique was the best. The only purpose of this method was to cauterize and to remove the inflammatory part of the nasopharynx with 1% $ZnCl_2$ solution. (The solution was simply used for cauterization of the erosion of the mucous membrane.) Specific action of Zn^{++} or Cl^- was not expected at all. Similar effects were observed using $AgNO_3$, $CuSO_4$ and $ZnSO_4$.

The finding of nasopharyngitis can be done by understanding the relation between nasopharyngitis and various diseases related to nasopharyngitis mentioned in this thesis. Though nasopharyngitis is an easily understandable disease, it becomes difficult to understand when obstructed by old medical knowledge. Most of the diseases related to nasopharyngitis are of unknown origins or are called psychological and incurable. Therefore it is not easy to get an understanding of the relation between nasopharyngitis and these diseases. The nasopharyngeal treatment is not simply a method in otorhinolaryngology but an entirely new theoretical method in medicine.

Special mention must be made that those diseases, which were cured or abated by the nasopharyngeal treatment, were based on clinical experiences of the author.

1. The nasopharyngitis exists ignorantly in many persons.

2. Their existence however may be rarely proved by the routine otolaryngological observations.

3. This may be the reason why nasopharyngitis has not been discussed in the past medicine.

4. The diagnosis of this inflammation is carried out only by the direct abrasion of the nasopharynx mucous membrane.

5. By the local treatment of this nasopharyngitis, following facts are discovered. The treatment of nasopharyngitis causes the improvement of the target diseases.

6. Projection of pain. The nasopharynx wall is not so sensitive for the pain locally but the pain is often projected to the distant area as the dull irritation such as headache. The localization of headache exactly corresponds to the inflammatory part of the nasopharynx wall.

7. The nasopharyngitis exists as the primary area of infection for the inflammation of the distant area, i.e. as the origin of the focal infections, autoimmunizations or collagen diseases like the inflammation of tonsils or others. These facts are certified by the pursuit of progress of the target diseases during the treatment of nasopharyngitis.

8. This pursuit is also effective for the discovery of mechanism of a disease whose origin is not clear.

9. The nasopharynx stimmulation often causes general excitement of the autonomic nervous system. This can be observed through the finger tip plethysmography or the blood pressure change directly after the nasopharynx stimmulation.

10. Nasopharyngitis is often accompanied with autonomic nervous disorders. This can be clarified by the same method as the previous examination in the cases of autonomic nervous disorders.

11. The local treatment of this nasopharyngitis which is accompanied with the autonomic nervous disorders may improve this disorders to be normal, i.e. the autonomic nervous disorders can be controlled by the nasopharynx treatment.

12. Various kinds of uncertain complaints

(so called the diseases of autonomic nervous disorders) are cured by the nasopharynx local treatment

13 The allergic attacks of various kinds are often removed completely by the local treatment of the accompanied nasopharyngitis. This may be due to the sedation of the autonomic nervous excitability which is considered to accerelate the allergic attacks.

14 The nasopharynx stimulation accerelates the alteration of the body fluid. Especially when there exists severe inflammation in the nasopharynx, this phenomenon occurs remarkably.

The alteration of euglobulin lysis time (E.L.T.) free fatty acid in the blood and a part of γ-globulin were studied. Also the hormone secretion in the blood was studied. Plasma 11-OHCS (steroid) increases remarkably immediately after the stimulation of the inflammatory nasopharynx. This fact seems to reveal the mechanism of inflammatory disease a little more precisely.

Also the morphological component of the blood alters by the same procedure. Remarkable increase of thrombocytes was observed direct after the abrasion of the inflammatory nasopharynx in a case of the thrombocytopenic purpura. (This case is not yet discribed in this paper.)

(so called the diseases of autonomic nervous disorders) are cured by the nasopharynx local treatment.

13 The allergic attacks of various kinds are often removed completely by the local treatment of the accompanied nasopharyngitis. This may be due to the sedation of the autonomic nervous excitability which is considered to accerlate the allergic attacks.

14 The nasopharynx stimulation accelerates the alteration of the body fluid. Especially when there exists severe inflammation in the nasopharynx, this phenomenon occurs remarkably.

The alteration of euglobulin lysis time (E.L.T.) free fatty acid in the blood and a part of γ-globulin were studied. Also the hormone secretion in the blood was studied. Plasma 11-OHCS (steroid) increases remarkably immediately after the stimmulation of the inflammatory nasopharynx. This fact seems to reveal the mechanism of inflammatory disease a little more precisely.

Also the morphological component of the blood alters by the same procedure. Remarkable increase of thrombocytes was observed direct after the abrasion of the inflammatory nasopharynx in a case of the thrombocytopenic purpura. (This case is not yet discribed in this paper.)

PREFACE

All papers in this particular issue are dedicated to Professor Tadashi Fukuda by his friends and students to commemorate his retirement as Director of the Department of Otorhinolaryngology Gifu University School of Medicine, Japan, in April, 1974.

Subsequent to his graduation from Kyoto University School of Medicine in 1945, Professor Fukuda initiated his vestibular investigations under Professor Teiji Hoshino who was a real pioneer of neuro-otology in Japan. In 1952 Dr Fukuda was appointed Professor and Chairman of the Department of Otorhinolaryngology Gifu University School of Medicine. Since that time, his research activities have been basically for the investigation of equilibrium function. Professor Fukuda's name is very well known not only within the otological field but also in many related areas for his blind-folded vertical writing test and stepping test which have been extensively utilized by clinicians for the purpose of vestibular examination. His works on the postural reflexes were very well summarized in his masterpiece "Studies on Human Dynamic Postures from the Viewpoint of Postural Reflexes" which was published as a supplementum of the Acta Otolaryngologica in 1961.

In addition to developing his own department extensively Professor Fukuda made a strong effort to create the "Institute of Equilibrium Research" which was established in 1971 to be closely affiliated with Gifu University School of Medicine. Professor Fukuda was named the first director of this important institute. This fact proves that he is such an ambitious scholar in the field of vestibular researches and actually he donated all of himself all of his energies and efforts for the development of equilibrium researches. Furthermore, no one can deny that he is not only a brilliant and imaginative scientist but also a very sensitive humanist and an artist. Presently Professor Fukuda is an honorary member of Japan Society of Equilibrium Research and he is one of its most active members.

Professor Hinoki, Professor Watanabe, and I initiated the collection of commemorative papers and upon our request twenty manuscripts were contributed. I would like to express my sincere appreciation to all contributors for their warm thoughtfulness and friendship which they have shown to Professor Fukuda.

POSTURAL BEHAVIOR AND MOTION SICKNESS[1]

Tadashi Fukuda

From the Department of Otorhinolaryngology Gifu University School of Medicine Gifu, Japan

Abstract. (1) An interesting style of acting was demonstrated on a stage of Kyogen, classic comedy of Japan, titled Funawatashimuko (A boatman and bridegroom in boat" Antagonistic postures which move toward the opposite direction were displayed by boatman who is pulling an oar and passenger who is being moved by the rolling of a boat. (2) Why doesn't one suffer from motion sickness when he drives car but may suffer from it hen he is passenger? This question was answered, from the standpoint of human postures, by observing the antagonistic postures exhibited by bus-driver and passenger and also by the findings in postrotatory eye nystagmus (an indication of artificial motion sickness) which was varied according to the three different positions of the head. (3) Learning postural adjustment against motion sickness, developing through repetitively traveling in vehicles, was also objectively shown in posture of an experienced lady bus-conductor whose body inclined in the same direction as that of the driver. Its similarity to the establishment of kinetic labyrinthine reflex in chickens as explained.

Ladies and Gentlemen!

Several years ago, I happened to be watching a very interesting Kyogen (a very old traditional comedy of Japan) entitled Funawatashimuko i.e., A bridegroom and a boatmen in a boat" The comedy was very delightful and it was shown on a New Year's television program. At that time, I had been working on the problem concerning the relation between sea sickness and human postures, and I was deeply impressed by the style in which the actors portrayed the bodily movements of men in a boat, a style of acting which has remained unchanged for 500 years. In order to explain more clearly the relationship between motion sickness and human posture, a demonstration will be given on this stage at the opening ceremony The Shigeyamas, the head family of Kyogen in Kyoto have accepted to perform this comedy much to my pleasure Before the curtain is raised, I would like to emphasize a few important points. Very briefly the story behind this Kyogen goes as follows. A bridegroom is going to visit the parents of his bride and must cross the Biwako Lake in a small boat (like a Venetian gondola) There is a boatman with an oar in his hand waiting on the shore for passengers on his row boat.

A bridegroom who is carrying with him a sealed keg of Sake to be presented to the bride's father hires this boatman. Because the weather is very cold and windy the boatman who is an admirer of Sake (or an elbow bender), repeatedly asks for a cup of Sake. Of course, the bridegroom ignores the request. The boatman is very thirsty and refuses to continue rowing until finally the disgusted bridegroom gives him a cup of Sake by unsealing the keg. As the play continues, the bridegroom who is also an elbow bender becomes thirsty and drinks up all the Sake from the keg with the rather annoyed boatman. The important point which I wish to show and emphasize in this play is each posture of the boatman who is rowing and of the passenger on the boat being moved by rowing. Now let me show you the point by figures!

As you see in Fig. 1 the boatman stretches his upper extremities to push the oar bending forward, his posture inclines to your left. In contrast, the bridegroom inclines in the opposite direction, to your right. Thus the direction

POSTURAL BEHAVIOR AND MOTION SICKNESS[1]

Tadashi Fukuda

From the Department of Otorhinolaryngology, Gifu University School of Medicine, Gifu, Japan

Abstract. (1) An interesting style of acting as demonstrated on a stage of a Kyogen, a classic comedy of Japan, titled Funawatashimuko i.e., A boatman and bridegroom in boat. Antagonistic postures which move toward the opposite direction are displayed by boatman who is pulling an oar and a passenger who is being moved by the rolling of boat. (2) Why doesn't one suffer from motion sickness when he drives car but may suffer from it when he is a passenger? This question was answered, from the standpoint of human postures, by observing the antagonistic postures exhibited by bus-driver and passenger and also by the findings in postrotatory eye nystagmus (an indication of artificial motion sickness) which was varied according to the three different positions of the head. (3) Learning postural adjustment against motion sickness, developing through repetitively traveling in vehicles, as also objectively shown in posture of an experienced lady bus-conductor whose body inclined in the same direction as that of the driver. Its similarity to the establishment of tonic labyrinthine reflex in chickens was explained.

Ladies and Gentlemen,

Several years ago, I happened to be watching a very interesting Kyogen (a very old traditional comedy of Japan) entitled "Funawatashimuko" i.e., "A bridegroom and a boatmen in a boat". The comedy was very delightful and it was shown on a New Year's television program. At that time, I had been working on the problem concerning the relation between sea sickness and human postures, and I was deeply impressed by the style in which the actors portrayed the bodily movements of men in a boat, a style of acting which has remained unchanged for 500 years. In order to explain more clearly the relationship between motion sickness and human posture, a demonstration will be given on this stage at the opening ceremony. The Shigeyamas, the head family of Kyogen in Kyoto have accepted to perform this comedy much to my pleasure. Before the curtain is raised, I would like to emphasize a few important points. Very briefly the story behind this Kyogen goes as follows. A bridegroom is going to visit the parents of his bride and must cross the Biwako Lake in a small boat (like a Venetian gondola). There is a boatman with an oar in his hand waiting on the shore for passengers on his row boat.

A bridegroom who is carrying with him a sealed keg of Sake to be presented to the bride's father hires this boatman. Because the weather is very cold and windy the boatman who is an admirer of Sake (or an elbow bender), repeatedly asks for a cup of Sake. Of course, the bridegroom ignores the request. The boatman is very thirsty and refuses to continue rowing until finally the disgusted bridegroom gives him a cup of Sake by unsealing the keg. As the play continues, the bridegroom who is also an elbow bender becomes thirsty and drinks up all the Sake from the keg with the rather annoyed boatman. The important point which I wish to show and emphasize in this play is each posture of the boatman who is rowing and of the passenger on the boat being moved by rowing. Now let me show you the point by figures!

As you see in Fig. 1 the boatman stretches his upper extremities to push the oar bending forward, his posture inclines to your left. In contrast, the bridegroom inclines in the opposite direction, to your right. Thus the direction

[1] This paper was read at the opening ceremony of the 73rd Congress of Japan Society of Otorhinolaryngology held in Gifu City 1972 by the author who was the President.

Fig. 1 The boatman, who is standing, stretches his upper extremities to an oar bending forward and his posture inclines toward your left. On the contrary the sitting bridegroom inclines in the opposite direction, being moved by the roll and his posture inclines toward your right. Thus the directions of postural inclination in a boat are opposite to each other

of inclination of the two postures in the boat are opposite each other As the rowing action continues, the inclination of the posture of the two individuals changes direction as shown in Fig. 2. The boatman who is pulling the oar bends backward, i.e., the posture inclines to your right while the posture of the bridegroom inclines toward your left. This alternating pattern of individual posture continues changing rhythmically as the rowing continues. When on the stage, the boatman and the bridegroom move in opposite directions rhythmically the audiences feel just as if they saw a boatman and a passenger in a real boat hurrying its way through the waves of the Biwako Lake The reason why such a realistic impression is imparted by this highly stylized performance of the play can be found in the style of performance in which the postures of the two men incline to the opposite direction alternately a style which has probably been handed down generation after generation Now let us consider the movement of a boat as played in the theatrical performance shown in Figs 1 and 2. The boat is moving straight from the back of the stage toward the audience This movement of the boat is made possible by the work of a boatman who pushes and pulls an oar alternately with a delicate twist of the wrists. As the boat moves forward, it also undergoes a partial rotation (roll) along its longitudinal axis. It must also be noted that the movement of body of the boatman is in the same phase as the longitudinal rotation (roll) of the boat and that of the passenger is in the opposite direction to the rolling movement of the boat. Thus the behavior of the movement of two men in a boat is played in this example from the theatrical performance of a Kyogen play Recently I had a chance to see the staging of one of Japan's modern dances which portrayed the actions of a boatman and a passenger in the same boat. In this play the boatman who was

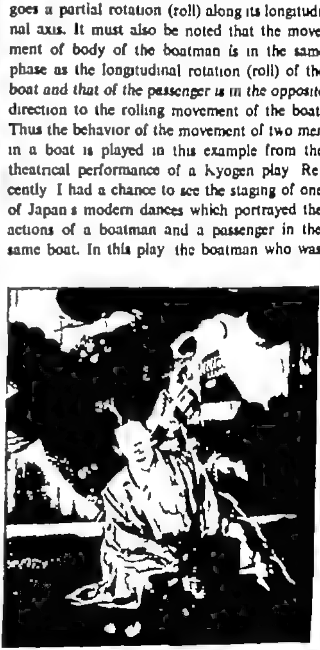

Fig. 2. As the rowing action continues, the direction of postural inclination changes to the opposite sides. The head and trunk of the boatman who is pulling the oar bends backward, i.e. the posture inclines toward your right, while the bridegroom inclines toward your left. Thus the two postures move into opposite directions.

...wing the boat and the passenger who was ...ing moved by the rolling of the boat, swayed ... the same direction, i.e., both moved to your ...ght or left at the same time. Looking at this ...odern dance, I was impressed by the accuracy ...ith which our ancestors had translated a segment ...f real-life behavior to the artificial settings of the ...tage.

Similar contrasts in bodily postures, such as ...hat just illustrated for a boatman and a passen... ...ger can be observed in our daily life. For example, as shown in Fig. 3, the head and trunk of a driver of a bus inclines toward the right when he revolves the handle to his right in order to turn the bus to the right, while the head and trunk of a passenger in the same bus inclines toward the left. Thus, the postures of the two individuals incline in opposite directions. From the viewpoint of centrifugal force, it is interesting to note that the driver deviates across the midline against the centrifugal force, showing a centripetal posture, while the passenger deviates across the midline in the direction opposite to the rotation of the bus, showing a centrifugal posture. Thus opposite postures are clearly evidenced between a driver and passenger in a bus. It is very important to remember that these contrasting postures are not the products of actors on a stage, but are real physiological phenomena caused by the movement of a bus which curves to the right.

The author would like to emphasize that such antagonistic patterns of postures as seen with a driver and a passenger in a moving bus as well as a boatman and a passenger (bridegroom) in a boat on a symbolic stage of Kyogen is deeply related to the cause of motion sickness. A driver as well as a boatman does not normally suffer from motion sickness while a passenger often times does. Moreover, we hear that one does not get motion sickness when he drives a car but when he is in a car as a passenger he does get it. Why is there such a difference concerning motion sickness between a driver and a passenger even though they are in the same car and subject to the same movement? The author would like to demonstrate that the difference is

Fig. 3. The head and trunk of the driver of a bus incline toward your right when he revolves the handle in a clockwise direction to make a right turn, while the head and trunk of a passenger in the same bus incline toward your left. Thus the two postures incline toward opposite directions from each other

due to the difference in the postures in which the bodies incline in the opposite directions and cross each other by introducing the following observation and experiment.

Güttich (1940) had observed that the position of the eyes and head of a human being is antagonistic in active and passive rotations. When a person begins to rotate around his own long axis, the eyes and the head deviate in the direction of rotation over the midline of the body and continue in this position during the period of the rotation accompanied by eye nystagmus. That is, an active rotation of a person is preceded by the eyes and head which deviate in the direction of rotation. However when a person on a chair is rotated passively the eyes and head *deviate against* the direction of rotation over the midline of the body and continue in this position accompanied by eye nystagmus during the *period* of the rotation, i.e., the eyes and head

remain in the direction opposite the rotation of a chair during a passive rotation Thus, with active rotation, the position of the eyes and head deviates in the direction of the rotation while with a passive rotation it deviates against the direction of the rotation of a chair In this way each position assumes an antagonistic, symmetric posture over the midline of the body

This antagonism is observed not only during rotatory movement around one's own axis but also in other linear and circular movements and it stands as a general rule of postures differentiating active and passive movements of human beings. For example when a runner on a track comes to a curve his posture inclines toward the inside of the curve and he assumes a centripetal posture However as seen in Fig. 3 a passenger who is every inch passively moved in a bus assumes a posture which deviates to the outside of a curve due to the action of the centrifugal force Thus the antagonism of the posture is also evidenced between a runner and a passenger i e between active and passive movements at a curve in human.

It is of interest to examine the posture of the driver in Fig. 3 from the standpoint of the Gütich's observation The driver does not assume a centrifugal posture such as seen in the passenger the driver assumes the same centripetal posture as a runner going around a curve Although the passenger and driver are in the same bus the position of the head and trunk of the former deviates in a direction opposite to the curve while that of the latter deviates in the same direction The two postures incline in opposite directions from each other and assume antagonistic positions. Now returning to why a person when driving a car does not suffer from motion sickness while he may do so when he is a passenger in a car To answer this question the author hypothesized that this is due to the contrast in assumed postures between drivers and passengers. To test this hypothesis the following investigations were performed

Postrotatory nystagmus after 10 rotations in 20 seconds was adopted as an indicator of motion sickness, based on the following theory Postrotatory nystagmus is a phenomenon arising from transient artificial labyrinthine ataxia caused by repeated rotations with which human beings are not familiar Postrotatory sensation is that of vertigo or illusion, i.e a transient motion sickness in which one feels as if still being rotated after the end of the rotation In other words, the rotation test is a method for measuring the time required by a subject on whom unexperienced passive repeated rotations are imposed, to regain almost normal equilibrium of the body after transient labyrinthine ataxia. Postrotatory nystagmus and sensation may be observed as the symptoms of artificial motion sickness which are often accompanied by nausea. So the recorded duration and the number of beats of postrotatory eye nystagmus, serve as an objective index of artificial motion sickness and its magnitude

The chair was designed to turn in a complete circle, in clockwise as well as counter clockwise horizontal direction, and constructed to allow a subject's head to be held in different positions. Seventy healthy adults, male and female without any ear diseases were rotated 10 times in 20 seconds in a counter clockwise direction During rotation the eyes were closed and the head was fixed in 3 different positions as follows first head position normal, i e 30 prone (nose down) position from the German horizontal plane second head position extreme left i e., toward the direction of chair rotation and third head position extreme right, i.e against the rotation of chair In each of the positions, the head was firmly fixed with a band to the head holder attached to the turning chair and the subject was rotated three sequences with 5 minute intervals. Immediately after each rotation the eyes were opened and the examiner calculated the duration and beats of postrotatory nystagmus which showed marked decrease and increase according to the difference of the head position as shown in Fig. 4 In the case of the first head position, i.e., the normal head position the numerical mean value of postrotatory nystagmus for 70 subjects was 27 beats in 21 seconds. With the head positioned in extreme left (the

second head position), it was 21 beats in 16 seconds, and in the third position, against the direction of chair rotation, it was 39 beats in 25 seconds. To summarize, by fixing the head toward the direction of chair rotation (the second head position) the mean value of duration and beats of postrotatory nystagmus decreased markedly compared with the effect of fixing the head in normal head position (the first head position). In contrast, by fixing the head against the direction of chair rotation (the third rotation), it increased markedly.

It is very interesting to examine the results from the viewpoint of Güttich's observation described above that during active rotation the position of the eyes and head deviates toward the direction of rotation, while, during passive rotation, it deviates against the direction of rotation. In the present experiment, each rotation was performed passively by turning a chair. However, the head was fixed in three different positions based on the following assumption. The first head position, which is the normal position of old Barany rotation, was adopted as the standard position. In the second rotation, the head of a passively rotated subject was fixed in the same position as in a subject who turns actively along his own axis. In the third rotation, the head was fixed against the direction of rotation. This is the head position of a subject during passive rotation in a chair in whom the head is not fixed during rotation. For the reason described above, the author would like to call the second head position, the active position of the head, and the third position, the passive position.

Fig. 3. A posture of an experienced lady bus-conductor while the bus is making right turn. Even being moved passively in a bus, her posture (head and trunk) inclined toward the right, i.e., in the same direction as that of the driver and opposite to that of a passenger shown in Fig. 3.

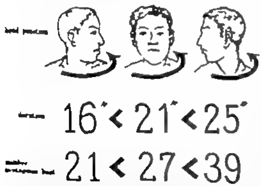

Fig. 4. With head rotated and fixed toward the direction of chair rotation (the second head position), the mean value of duration in seconds and the number of beats of postrotatory nystagmus decreased markedly compared with the case in which the head was fixed in straight head position (the first head position). On the contrary, with head rotated and fixed opposite the direction of chair rotation (the third rotation), it increased markedly. Arrow: direction of chair rotation.

As shown in Fig. 3, the head and trunk of a driver incline toward the right, i.e., toward the direction of the center of the curve and assume a centripetal posture. This posture may be said to correspond with the second head position, i.e., active position of the head resistant to postrotatory nystagmus, namely a posture in which a subject rarely suffers from motion sickness. On the contrary the head and trunk of a passenger incline toward the left according to centrifugal forces and assumes a posture which is opposite the posture of a driver. The passenger's posture may be said to correspond with the third head position, i.e., passive position of the head

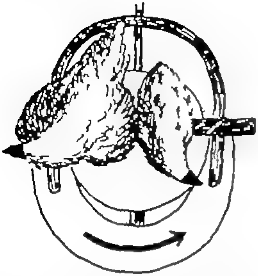

Fig 6 Trained (right) and untrained (left) chickens, 10 seconds after the beginning of rotation. The head of the trained turns in the same direction of rotation through the kinetic labyrinthine reflex, while the head of the un trained deviates still in the opposite direction of rotation by the static labyrinthine reflex (normal deviation).

vulnerable to postrotatory nystagmus, that is a posture in which one easily develops motion sickness. Thus the marked decrease and increase of postrotatory nystagmus observed in the above investigation clearly explains the fact that a subject who is driving a car hardly ever suffers from motion sickness while he easily gets it when he is a passenger in a car

Before summarizing the results, the author would like to add a few comments on the probl em of learned postural adjustment or habitu ation It is widely known that sailors or bus-conductors who have accumulated many years of experience in traveling on vehicles do not suffer from motion sickness. These people have developed special postural habits an example of which is illustrated in Fig 5 The author observed the posture of a trained lady bus-conductor who had been working in a bus for 5 years and made photographs of her back (without her knowl edge) while the bus was turning. When the bus is turned to the right, she assumed a posture with head and trunk inclined toward the right, i e exactly the same direction as the inclination of the driver While being moved passively in the bus, her posture inclined in a direction opposite to that of the passenger shown in Fig.

3 It is very interesting to note that the passenger and lady bus-conductor while sitting on seats in the same bus, took exactly opposite postures and inclined in an opposite direction from each other The lady bus-conductor took a posture similar to that of the driver whose posture was shown to be resistant to motion sickness. Thus a learned postural behavior or habituation is evidenced objectively in a lady bus-conductor who assumed an actively inclined posture toward the center of a curve, i e centripetal posture

This centripetal posture was reported by the author about 20 years ago under the title of Static and Kinetic Labyrinthine Reflex. Func tional development of labyrinthine function with rotatory training" (Fukuda, 1958) To summa rize the principal points shown in Fig. 6 blind folded leghorns were rotated 100 times in 200 seconds to both directions every day for two weeks. It was observed after repeated rotations that the birds, during rotation, turned their heads in the direction of rotation. This pheno-menon was never found in animals before re peated exposures to rotations. The labyrinthine function which caused it has been named the Kinetic labyrinthine reflex In contrast to this terminology the deviation of the head against the direction of rotation has been called the 'Static labyrinthine function a reflex which was called "the normal deviation" to maintain the original position of the head The animal showed a functional progress in equilibrating function through the repeated exposures to ro-tation which were therefore termed training (Fukuda 1963). Thus a learned postural beha vior during rotation was evidenced objectively in the establishment of a kinetic labyrinthine reflex which is here again clearly observed in the posture of a trained lady bus-conductor

POSITIONAL ALCOHOLIC NYSTAGMUS (PAN) IN MAN FOLLOWING REPEATED ALCOHOL DOSES

Gunnar Aschan and Martin Bergstedt

From the Department of Otolaryngology, Regional and University Hospital, Linköping University, Sweden

Flourens (1842), in animal experiments, and Joffroy & Servaux (1897), in man, showed that among other symptoms alcoholic intoxication brought about a nystagmus. Bárány (1911) and Bárány & Rothfeld (1913) found that this nystagmus was influenced by the position of the head of the test subject. Clinical observations regarding alcoholic nystagmus were made by Frenzel (1939), Pienkers (1943) and Walter (1954).

In a series of experiments on alcoholic intoxication in man, Aschan et al. (1955, 1956), Aschan (1958) and Aschan et al. (1958, 1964) showed that the appearance of PAN followed a very distinct and characteristic pattern. When a single dose of alcohol was given, PAN appeared in two phases, PAN I and PAN II separated by an intermediate period. PAN I had a latency of less than half an hour and lasted for 3–4 hours. During this phase the beating direction of the nystagmus was to the right when the head was in the right lateral position, when recorded behind closed eyelids, and to the left when the head was in the left lateral position. The intermediate period followed, in which no nystagmus was observed, and this lasted for 1–2 hours before the second phase began. PAN II thus had a latency time of 5–6 hours from the intake of alcohol. *The direction of PAN II was reversed*, i.e. it beat to the left when the head was in the right lateral position of the head, and vice versa. The duration of PAN II and also the intensity of both PAN I and PAN II were, however proportional to the maximal blood alcohol concentration and hence to the amount of alcohol consumed. PAN II always persisted for several hours after all alcohol had disappeared from the blood. Maximal blood alcohol concentrations above 0.25–0.40 per mille were sufficient to produce both phases of PAN. When this concentration was above 0.80 per mille, another type of nystagmus caused by eccentric fixation and *not* by the position of the head, viz. alcohol gaze nystagmus (AGN) was observed (Aschan, 1958).

The results of experiments in patients with unilateral labyrinthine destruction (Aschan et al., 1964) gave the following results.

An interaction occurred between an existing vestibular nystagmus of labyrinthine origin and a subsequent PAN caused by alcoholic intoxication. During alcoholic intoxication the two nystagmus phenomena resulted in a manifest nystagmus, which could be described as the algebraic sum of both the intensity and the beating direction of the known pre-experimental vestibular nystagmus and the subsequent PAN. *This meant that the resulting nystagmus was* increased when both nystagmus phenomena had the same beating direction and decreased when these directions were opposite. In the latter case an increasing intensity of PAN could either reduce the spontaneous nystagmus to a lower intensity, make it disappear completely or even make it change its beating direction.

A closer analysis of the timing of PAN I and

This investigation was supported by the Swedish Medical Research Council, Project 17X-36-03.

PAN II after a single dose of alcohol by correlation to blood alcohol curves obtained in earlier experiments allowed the hypothesis that the appearance of the different phases of PAN were dependent on the rise or fall of the blood alcohol curve

It seemed to be of interest, therefore, to study the PAN phenomena appearing after the administration of repeated alcohol doses, when an interaction between the two nystagmus phenomena PAN I and PAN II was likely to occur

The *aim* of the present investigation was

1 To study the courses of PAN I and PAN II after the administration of *repeated controlled alcohol doses* The PAN observations had to be carefully correlated to the blood alcohol concentration curves.

2. To analyse the possible mechanism of action of the elicitation of PAN phenomena and the interaction between PAN I and PAN II

METHODS

The nystagmus was recorded by the technique described by Aschan (1955) and Aschan et al. (1956) This method for electronystagmography has the advantage that the recordings can be made without fixation, thus eliminating any inhibition of the vestibular nystagmus by visual factors. A 10 degree calibration in the plane of the electrodes makes it possible to evaluate not only the beating direction but also the intensity of the nystagmus. Of the parameters obtained, the eye speed in the slow phase of nystagmus has proved to be of most value Its advantages have been demonstrated in the earlier studies both concerning PAN and clinical observations. Besides their documentation value the 30–40 nystagmus records from one experiment of long duration can easily be correlated to the blood alcohol concentration in a single graph At each point of observation recordings were made in the supine, right lateral and left lateral position of the head AGN observations were made only in the supine position with open eyes and 30 eccentric lateral fixation

The blood alcohol concentration was determined by the Widmark micro-method (1932) or by the enzymatic AD-method. Triplicate samples of 0 1 ml blood were withdrawn at intervals of 30–60 minutes. The experimental error of a triplicate sample was $\pm 0\,03$ per mille [1]

The alcohol whisky administration was varied in order to produce three different types of changes in the blood alcohol concentration

1 *Two single doses* with the second one so arranged in time that it should coincide either with the initial PAN I the intermediate period or a manifest PAN II caused by the first dose. The interval between the two doses thus varied from 4–9 hours The initial dose of whisky varied from 100–200 ml, and the second dose from 50–150 ml.

2. *Repeated small single doses*, to vary the rate and time of absorption Thus 180–540 ml whisky divided in 8–18 doses were given over a period of 3–6 hours.

3 A moderate dose followed by small doses, in an attempt to *maintain a constant blood alcohol level* over a fairly long period of time. Following a primary dose of 120–140 ml whisky 330–440 ml divided in 21–25 doses of 10–30 ml each were given over a period of 9–11 hours.

Experiments with one single dose in test subjects used in previous investigations served as a pilot study Experiments with alcohol intake over such long periods as 11 hours or more could not be carried through without giving some food thus introducing factors which influenced the alcohol absorption

MATERIAL AND PROCEDURE

The test subjects were healthy females and males with moderate drinking habits. The age distribution was 19–31 years. In all subjects the neuro-otological findings, including pure tone audiograms, were normal. Many of the subjects had participated in earlier single dose experiments. A total of 43 experiments were performed on 38 test subjects. Each experiment started early

1 per mille ~ 1 mg/g = 0.1 per cent 100 mg 0.0.2 moles alcohol/l.

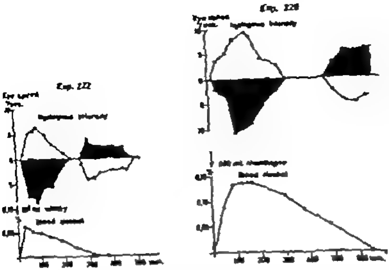

Fig. 1. Experiment 222 and 226. Blood alcohol curves and PAN observations after single doses of alcohol. In experiment 222 with plain whisky the blood alcohol curve has a marked peak, whereas the diluted alcohol in experiment 226 gives a slow change-over from rising to falling blood alcohol. In the nystagmus intensity diagram the observations from the right lateral position of the head are above the zeroline, those from the left lateral position below. White areas right beating nystagmus, black areas left beating. Thus PAN I = white over black areas, and PAN II = black over white areas.

in the morning, no food having been taken since the previous night. During the 10–26 hours that the experiment lasted, repeated tests for PAN and blood alcohol were carried out at intervals of 30–60 minutes. The results given in this communication are based on over 3 000 separate nystagmus recordings and 4 000 blood alcohol tests.

RESULTS

. One single dose

As an introduction the two experiments in Fig. 1 are presented. They are taken from other investigations but will serve as a guide for the subsequent figures. Both refer to single doses of alcohol. In experiment 222, 120 ml whisky and in experiment 226 half a litre of champagne was consumed within 15 minutes. In both experiments the two phases of PAN are easy to recognize and to correlate to the blood alcohol curves. The stronger liquor in experiment 222, compared with the diluted alcohol given as champagne in experiment 226 results in quite different blood alcohol curves especially regarding the change-over from increasing to falling blood alcohol concentration. In experiment 222 the curve shows a pronounced peak, whereas in experiment 226 the change is more gradual. Although the present investigation was restricted to pure whisky some of the test subjects could only take the whisky diluted with some water which was immediately reflected in the blood alcohol curves. For example the peak from the blood alcohol curve of experiment 222, Fig. 1 expected in two single dose experiments, is missing in experiments 171, 152 and 95 (Figs. 3, 5 and 2 respectively). Here the diluted whisky gives curves which are more similar to that for champagne.

B. Two single doses

A total of 20 experiments of this type were carried out. The two doses will be referred to as primary and secondary, as also will the different phases of PAN that could be attributed to a particular dose. The primary dose varied from 100–200 ml whisky, and the secondary from 50–150 ml. The intake of the secondary dose was timed according to the primary PAN phenomena observed so that it would interfere

The results given in this communication are based on over 3 000 separate nystagmus recordings and 4 000 blood alcohol tests.

RESULTS

A. *One single dose*

As an introduction the two experiments in Fig. 1 are presented. They are taken from other investigations but will serve as a guide for the subsequent figures. Both refer to single doses of alcohol. *In experiment 222, 120 ml whisky* and in experiment 226 half a litre of champagne was consumed within 15 minutes. In both experiments the two phases of PAN are easy to recognize and to correlate to the blood alcohol curves. The stronger liquor in experiment 222 compared with the diluted alcohol given as champagne in experiment 226 results in quite different blood alcohol curves especially regarding the change-over from increasing to falling blood alcohol concentration. In experiment 222 the curve shows a pronounced peak, whereas in experiment 226 the change is more gradual. Although the present investigation was restricted to pure whisky some of the test subjects could only take the whisky diluted with some water which was immediately reflected in the blood alcohol curves. For example the peak from the blood alcohol curve of experiment 222, Fig. 1 expected in two single dose experiments, is missing in experiments 171, 182 and 95 (Figs. 3, 5 and 2 respectively). Here the diluted whisky gives curves which are more similar to that for champagne.

B. *Two single doses*

A total of 20 experiments of this type were carried out. The two doses will be referred to as primary and secondary as also will the different phases of PAN that could be attributed to a particular dose. The primary dose varied from 100–200 ml whisky and the secondary from 50–150 ml. The intake of the secondary dose was timed according to the primary PAN phenomena observed so that it would interfere

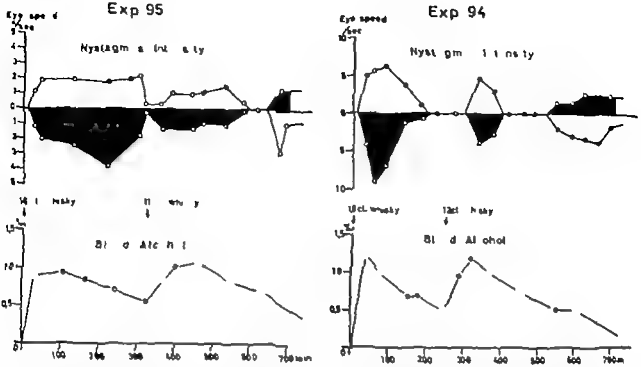

Fig 2 Two single doses of whisky In experiment 95 the *second dose was given at the end of a manifest PAN I* Despite the higher secondary blood alcohol maximum the last—secondary—part of PAN I has a shorter duration and a lower intensity In experiment 94 the second dose is timed to coincide with the primary intermediate *period. Despite the same secondary blood alcohol maximum* the secondary PAN I is shorter and of a lower intensity than the primary PAN I

(1) with the primary PAN I (2) with the primary intermediate period or (3) with an already manifest primary PAN II Thus there was a systematic increase *from 4 to 9 hours in the interval* between the intake of the two doses, this interval being adjusted according to the primary nystagmus observations in each experiment and to the desired point of interference of the three alternatives mentioned above

(1) A typical example of administration of the secondary dose just before the end of primary *PAN I is illustrated in Fig. 2, experiment* 95 The primary PAN I was very near to an end when the secondary dose elicited a secondary PAN I On comparing the primary and secondary PAN I it is seen that the secondary PAN I has a somewhat shorter duration and also a lower intensity than the primary The blood alcohol curve shows a higher secondary maximum. *Only the first part of a PAN II was re-*corded, but this appeared when the blood alcohol was decreasing.

(2) Administration of a secondary dose during the primary intermediate period is illustrated in Fig. 2, experiment 94 Here two separate PAN I were observed. In this experiment also the *shorter duration of the secondary PAN I com*pared with the primary is observed and here the reduction is more marked The intensity of the secondary PAN I is also lower than that of the primary despite the maximal blood alcohol concentration in the secondary peak. The duration of the secondary intermediate period was two hours PAN II appears, as in all experi*ments, with the final fall in the blood concen*tration The differences in the time of appearance of the primary phenomena and the necessity for adjusting the interval between the doses individually in each experiment are also clear on comparing the two experiments in Fig 2

(3) Typical examples of a secondary dose given during a manifest primary PAN II are given in *Fig. 3* experiments 171 and 172. In both experiments the secondary dose was about 1 3 of the primary one Here the primary PAN observa*tions were within the limits observed in earlier*

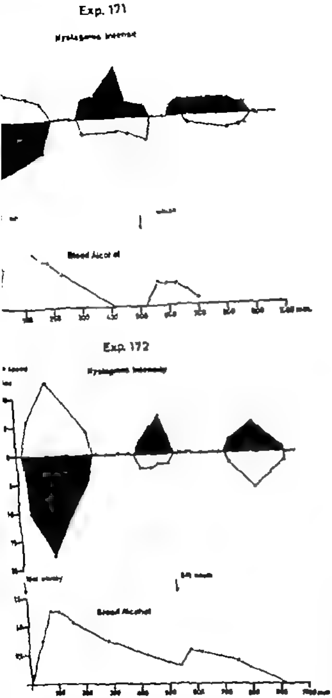

Fig. 3. Two single doses of whisky. The second dose is timed to coincide with a manifest primary PAN II, and in both experiments 171 and 172 this results in blocking of PAN for 1 hour and 3 hours respectively.

single dose experiments just until the secondary dose was taken. The secondary dose in both experiments resulted in a disappearance of the primary PAN II, in experiment 171 for a short period, and in experiment 172 for a longer period. This "blocking" of the primary PAN II by a secondary PAN I must have its explanation in the fact that the two have opposite beating

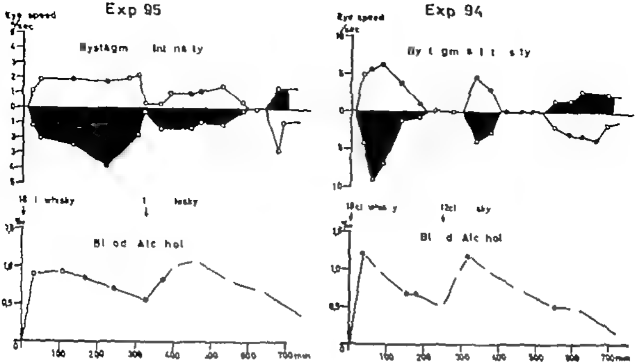

Fig 2. Two single doses of whisky In experiment 95 the second dose was given at the end of a manifest PAN I Despite the higher secondary blood alcohol maximum the last—secondary—part of PAN I has a shorter duration and a lower intensity In experiment 94 the second dose is timed to coincide with the primary intermediate period. Despite the same secondary blood alcohol maximum the secondary PAN I is shorter and of a lower intensity than the primary PAN I

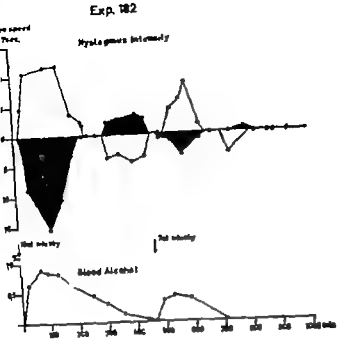
(1) with the primary PAN I (2) with the primary intermediate period or (3) with an already manifest primary PAN II Thus there was a systematic increase from 4 to 9 hours in the interval between the intake of the two doses, this interval being adjusted according to the primary nystagmus observations in each experiment and to the desired point of interference of the three alternatives mentioned above

(1) A typical example of administration of the secondary dose just before the end of primary PAN I is illustrated in Fig 2, experiment 95 The primary PAN I was very near to an end when the secondary dose elicited a secondary PAN I On comparing the primary and secondary PAN I it is seen that the secondary PAN I has a somewhat shorter duration and also a lower intensity than the primary The blood alcohol curve shows a higher secondary maximum. Only the first part of a PAN II was recorded but this appeared when the blood alcohol was decreasing.

(2) Administration of a secondary dose during the primary intermediate period is illustrated in Fig. 2, experiment 94 Here two separate PAN I were observed In this experiment also, the shorter duration of the secondary PAN I compared with the primary is observed and here the reduction is more marked. The intensity of the secondary PAN I is also lower than that of the primary despite the maximal blood alcohol concentration in the secondary peak The duration of the secondary intermediate period was two hours. PAN II appears, as in all experiments, with the final fall in the blood concentration The differences in the time of appearance of the primary phenomena, and the necessity for adjusting the interval between the doses individually in each experiment, are also clear on comparing the two experiments in Fig. 2.

(3) Typical examples of a secondary dose given during a manifest primary PAN II are given in Fig. 3 experiments 171 and 172. In both experiments the secondary dose was about 1 3 of the primary one Here the primary PAN observations were within the limits observed in earlier



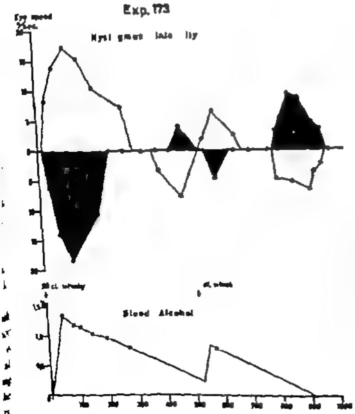


Fig. 5. Two further single dose experiments (182 and 173) with the same test subjects as in Fig. 3 (experiments 171 and 172, respectively). The comparatively higher secondary dose in both these experiments than in experiments 171 and 172 results in a secondary PAN I of a higher intensity and under these experimental conditions this results in a reversed beating direction of PAN over period of about 2 hours. With more frequent observations during the critical stage, an intermediate period is also observed.

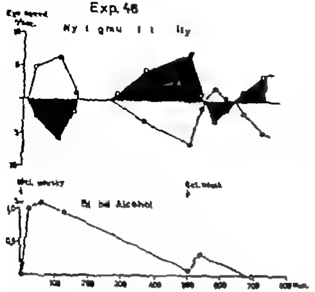

Fig 4 Experiment 46. Two single doses of whisky the second timed to coincide with a primary PAN II. In this test subject the second dose resulted in such an intense secondary PAN I that for about one hour not *only* was there blocking of PAN but also a change in beating direction.

directions. The two experiments 171 and 172 also confirm another earlier observation that the intensity of PAN I is dependent on the degree of alcoholic intoxication This is evident in the first part of the experiments. In experiment 171 the primary maximal blood alcohol concentra tion was 1 0 per mille, and in *experiment 172*, 1.35 per mille. As a result the primary PAN I in experiment 172 has a much higher intensity than that in experiment 171 This is also valid for the secondary PAN I. Thus, in experiment 171 a secondary blood alcohol maximum of 0 4 per mille resulted in blockade of the primary PAN II for 1 hour whereas in experiment 172 the higher secondary maximum of 0 6 per mille gave a block that lasted for 3 hours.

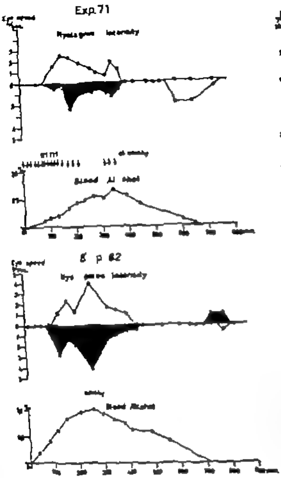
A third example of a secondary dose 1/3 of the first one, is illustrated in experiment 46, Fig. 4 Here the secondary dose gave a secondary blood alcohol maximum of 0.32 per mille In *this test subject*, however this dose was sufficient not only to block the primary PAN II but also to reverse its beating direction for a short period.

A quantitative factor regarding the intensity of the primary PAN was found on analysis in earlier experiments. *In the experiments in Fig 3* and 4 this also seems to be valid for the second ary *PAN* phenomena, but because of the indi vidual variations illustrated, with blocking alone of the primary PAN II in Fig. 3 and *blocking* combined with reversal of the beating direction in Fig. 4 we repeated the tests in the same test subjects.

Experiments 173 and 182 in Fig. 5 refer to the same test subjects as in experiments 172 and 171 (Fig. 3) respectively The principal change in the experimental conditions in Fig. 5 was that the secondary dose was kept higher in relation to the primary dose. This resulted in a secondary PAN I of a higher intensity and as a result the intensity of the secondary PAN I was higher for a period of about 2 hours than that of the primary PAN II *Thus* the primary PAN II not only disappears but also changes beating direction. The more frequent observa tions also showed a short interval without nystagmus—an interval during which the primary PAN II and the secondary PAN I were obviously of the same intensity and thus blocked each other

Figs. 3–5 are representative of the other experiments. They also show the individual *variations* which complicate statistical treatment of the material as a whole, the reason for which the results are documented in this way It is also worthy of observation that the way in which the whisky is taken influences the blood alcohol curve. Thus experiments 172 and 173 represent whisky taken undiluted, with peaks in the curves, and experiments 171 and 182 whisky taken diluted with water showing a slow change-over from rising to falling blood alcohol concentrations.

It is concluded that a quantitative factor exists in this type of experiment also A low secondary dose has only a blocking action on the primary PAN II while a higher dose results in a change in the beating direction over a short (exp 46) or long (exp 173 and 182) period of time Thus the results obtained by Aschan et al (1956) with single dose experiments, showing that the degree of intoxication influences the intensity of PAN I but not the duration, ha



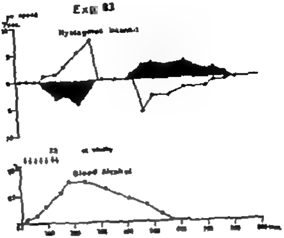


Fig. 6. Experiments 71, 82 and 93. Slow increase in the blood alcohol by repeated small doses over a fairly long period of time. The slower the increase in blood alcohol the longer the latency for PAN I. The duration of PAN I is also prolonged. It persists while the blood alcohol is still increasing and also continues for some hours during the descending part of the blood alcohol curve.

appeared, as the test subjects refused to participate any longer.

A reversed form of alcohol administration, i.e. small doses followed by a larger one, is illustrated in Fig. 7 (experiment 93). Seven 30 ml doses of whisky given over a period of 2½ hours gave a slowly rising curve with a blood alcohol maximum of 0.85 per mille after 3 hours. As in previous experiments, this caused a PAN I with a prolonged duration. A further single dose of 120 ml whisky in 5 hours induced a new rise in the blood alcohol to a maximum of 1.31 *per mille*. This caused a secondary PAN I of a rather short duration, a new and prolonged intermediate period lasting for 2½ hours, and finally a PAN II with a latency of 9½ hours and still persisting when the experiment was *discontinued*.

In principle the PAN findings in experiment 93, Fig. 7 are similar to those illustrated in experiment 94 Fig. 2. There are differences in intensity and timing, but the corresponding blood alcohol curves are similar in that they both show two blood alcohol maxima separated by a fall in concentration.

"Constant" blood alcohol levels

It was the aim of these experiments to produce a certain moderate blood alcohol level by giving the test subject an initial large dose of alcohol, and then to maintain this level by repeated small doses. In all eight experiments with an initial dose of 120–140 ml whisky followed by 10–25 doses of 10 ml occasionally 20 ml and sometimes an extra dose of 30 ml over a time of 8½–10½

proved valid even in this more complex experimental situation

Unfortunately these long experiments were rather tiring for the test subjects, and it was not always easy to persuade them to return for further experiments. This explains why some of the experiments were not carried to the absolute end of PAN II At the end of some long experiments we has difficulties in keeping the test subjects awake. Thus sleepiness sometimes resulted in poor recording at the end of PAN II and we would like to point out that this part of PAN II includes experimental errors and cannot always be assumed to be accurate in some of these experiments.

Repeated small doses

In previous investigations and in the experiments hitherto described in this study the alcohol intake started with a large dose. The result was a rapid rise in the blood alcohol concentration and the mean value for latency for PAN I was about 30 minutes. As the PAN findings seem to be closely related to the blood alcohol curves, the first problem was to determine whether and if so how a slow rise in the blood alcohol concentration influenced PAN

Repeated small doses of alcohol were given to 16 test subjects. Ten to eighteen 10–30 ml doses of whisky were given over a period of 3–5 hours. As seen from the graphs in Fig. 6 the doses given in experiments 71 82 and 83 chosen for illustrating the result brought about a slowly rising blood alcohol curve the maximum occurring after 3–6 hours, compared with 1/2–2 hours with larger single doses.

The latency for PAN I was prolonged in all these experiments. The slower the increase in the blood alcohol curve the longer the latency for PAN I the longest latency observed being 2 hours. On the other hand although the latency was delayed, PAN I appeared at blood alcohol concentrations as low as 0.1 per mille

It was anticipated that the slow absorption of alcohol with this type of administration would give this result Thus it seemed justified to check the conditions on the quickest possible increase in blood alcohol, i.e. by intravenous administration

Three patients were given a solution of 10 g alcohol per 1000 ml intravenously in a dose of 100 ml per 5 minutes. All three patients had a manifest PAN I after $8^1/_2$ minutes. Clinical experience with alcohol blockade (80 volumes per cent) for neuralgia has shown in every case tested (18 cases) a typical PAN I within 10 minutes.

The duration of PAN I was also prolonged, as seen for example in Fig. 6 (experiments 82 and 71) Thus duration was now 6–$7^1/_2$ hours, compared with 3–4 hours after a single dose.

The intermediate period was prolonged lasting for 2–4 hours compared with 1–2 hours after single doses, and started later as a result of the increased duration of PAN I and the prolonged latency for that phenomenon.

As a consequence of the observations just mentioned the latency of PAN II was prolonged. As expected, PAN II lasted in every case for several hours after the blood alcohol had returned to zero In the experiments presented in Fig. 6 PAN II stopped after 13–14 hours, whereas the blood alcohol had returned to zero after $9^1/_2$–12 hours.

For ethical reasons the increase of blood alcohol could not be carried above certain limits. However the results obtained, with a slow change-over from a rising to a falling blood alcohol concentration as late as 6 hours after the start of the experiments seem to have given us the information required.

Combined large and repeated small doses

Fig. 7 illustrates an experiment of this type (experiment 58) with the blood alcohol concentration increasing to a comparatively high value the maximum being 1 50 per mille after 5 hours. This increase resulted in a PAN I with a short latency but a duration of $7^1/_2$ hours, the duration showing essentially the same pattern as after the intake of repeated small doses as illustrated in Fig. 6. Experiment 58 had to be discontinued after $9^1/_2$ hours before PAN II

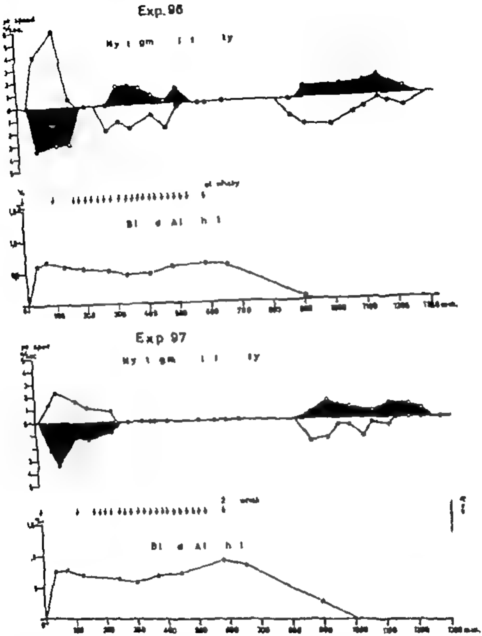

Fig. 8. Experiments 96 and 97. An attempt at producing "constant" blood alcohol levels. The latency, intensity and duration of PAN I are just as in the single dose experiments. Despite the attempt at constancy the blood alcohol curves still show two separate maxima. As result in experiment 96 the secondary maximum gives a secondary PAN I which blocks an already manifest primary PAN II. In experiment 97 the increase in blood alcohol concentration appears earlier and is rather more marked. Hence the primary PAN II and the secondary PAN I block each other for about [illegible] hours.

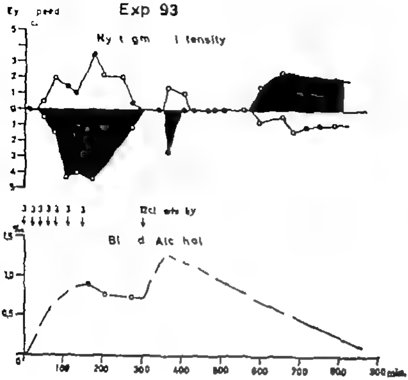

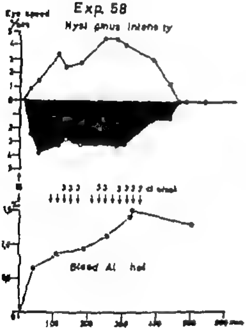

Fig 7 Experiment 58 shows an increasing blood alcohol concentration over a period of 5½ hours. Despite the ir regular alcohol intake the prolonged ascension of the blood alcohol curve explains the short latency the long duration of PAN I and the intensity In experiment 93 the irregular alcohol intake results in a blood alcohol curve with two separated maxima. The secondary maxi- mum coincides with a *primary intermediate period* and consequently the PAN findings, with a primary and secondary PAN I, are in principle the same as in Fig. 2 (Experiment 94).

hours was given The total amount of whisky consumed thus ranged from 330–430 ml

Four typical examples are illustrated in Figs. 8 and 9 However the blood alcohol curves in these experiments all show slight variations These may be partly explained by individual variations in rate of absorption or intake of food or beverage which had to take place during such prolonged experiments.

In spite of the large doses of alcohol given, i e 330–430 ml whisky the maximal blood alcohol levels were no higher than 0 45–0.95 per mille. The same amounts given as single doses, 1 6–1 9 g alcohol per kilo, would have produced maximal blood alcohol levels of 2.3–2.6 per mille

The material can be divided into two main groups, one with a rapid initial rise in blood alcohol concentration and a second with a slower rise caused by dilution of the whisky with water

Fig. 8 (experiments 96 and 97) illustrates two typical examples of a rapid initial increase in the blood alcohol concentration with a first maximum occurring in ~100 minutes. As ex pected, this resulted in a PAN I appearing with the usual latency of about 30 minutes. In experi

way as after a single dose of alcohol, but its duration was slightly above the mean in single dose experiments. The intermediate period here, however lasted for 9 hours and was followed by a PAN II which disappeared 4 hours after the blood alcohol had returned to zero.

The PAN observations in experiment 96 (Fig. 8) were in principle the same as those in experiments 171 and 172, illustrated in Fig. 3. In these latter experiments the blood alcohol curve showed two very pronounced maxima. The blood alcohol curves in experiments 96 and 97 also showed the two maxima, but here they are much less distinct than in the two large dose experiments.

Thus the explanation for the PAN findings in experiment 96 would seem to be that the secondary maximum in the blood alcohol curve results in a secondary PAN I during an already present primary PAN II. As the two nystagmus phenomena have opposite beating directions, this means that they level out each other

In experiment 97 the secondary maximum in the blood alcohol is reached at 10 hours after a slow secondary rise in the blood alcohol curve which starts as early as at 5 hours. According to the results already illustrated in Fig. 6, this slow increase in the blood alcohol over a period of 5 hours should result in a prolonged PAN I. The primary PAN II and the secondary PAN I due to the rise in blood alcohol from 5–10 hours also have opposite beating directions. Obviously they must have about the same intensity and consequently they level out each other The prolonged PAN I observed on continuous rise in blood alcohol over a long period of time, combined with an ordinary intermediate period, explains why in experiment 97 no PAN is recorded over a period of 9 hours.

Experiments 64 and 67 (Fig. 9) show a comparatively slow rise in the first part of the blood alcohol curve despite the larger initial dose. As a result the latency for PAN I is slightly above the average in both experiments.

In experiment 64 the maximum in the blood alcohol concentration curve is delayed and the first slight fall is seen after 6 hours. This explains the long duration of PAN I which ends at 9 hours. A second hardly noticeable rise in the blood alcohol at 11 hours gives a prolonged intermediate period of about 3 hours, after which PAN II starts and persists for more than two hours after the blood alcohol has returned to zero.

PAN I is also prolonged in experiment 67 but not as greatly as in experiment 64 Here the first maximum in the blood alcohol curve also occurs earlier After an intermediate period PAN II starts in the left lateral position and then disappears again. This must result from the secondary rise in the blood alcohol concentration with a second maximum at 8 hours. Even such a very slight rise seems to be enough to produce a secondary PAN I which levels out the primary PAN II for three hours. PAN II then persists for 5 hours after the blood alcohol has returned to zero

As can be seen in Fig. 8 and 9 the PAN findings in this last group of experiments vary somewhat. In all of them, however it may be said that the blood alcohol curves give a key which explains the differences in PAN The occurrence of different blood alcohol maxima, especially and even increases in the blood alcohol of only 0.1–0.2 per mille over several hours are sufficient to cause interactions between the secondary PAN I and primary PAN II phenomena. Thus all results of this kind can be explained by correlating the PAN findings with the blood alcohol curves. It may be worth stressing that PAN I always appeared at the start of the experiment and that all experiments ended with a PAN II lasting for a considerable length of time after the blood alcohol had returned to zero.

DISCUSSION AND CONCLUSION

In the introduction the standard values obtained in earlier investigations on PAN after single doses were given (Aschan, Bergstedt, Goldberg & Laurell, 1956). The interaction between spontaneous vestibular nystagmus and PAN was also described in detail (Aschan, Bergstedt &

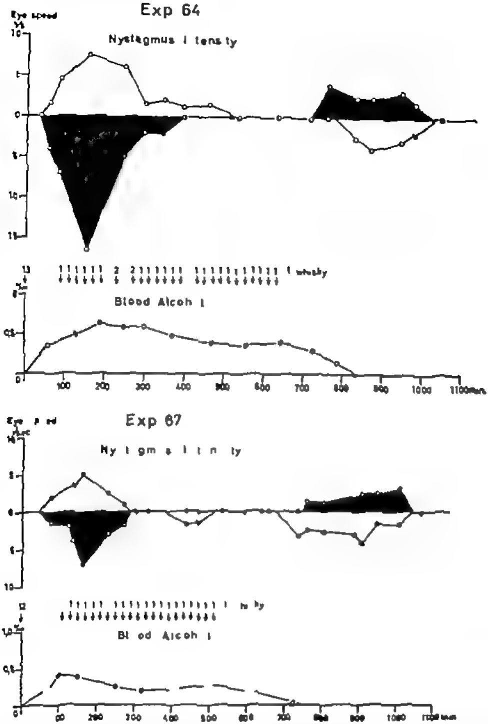

Fig 9 Experiments 64 and 67 both show a slow rise in the blood alcohol curve, resulting in prolonged latency for PAN I In experiment 64 the late primary blood alcohol maximum gives prolongation of PAN I and the secondary ha dly noticeable rise gives a prolonged nter mediate period. In experiment 67 the first blood alcohol maximum appears earlier than in experiment 64 thus the duration of PAN I is shorter The slightly pronounced secondary blood alcohol maximum in experiment 67 occurs just after the first appearance of the primary PAN II, with consequent blocking of the two PAN phases for nearly three hours, the result being a secondary inter mediate period. Note the long duration of PAN II in both Figs. 8 and 9 after the blood alcohol has returned to zero

ment 96 this PAN I lasted for the usual length of time and after a normal intermediate period PAN II appeared. This PAN II ended at about $9^1/_2$ hours and for a period of nearly 5 hours no PAN was observed. After this a secondary PAN II was manifest, and persisted about 6 hours after the blood alcohol had returned to zero

In experiment 97 PAN I appeared in the same

the last drink. Last but not least, the intermediate period reduces the possibilities of using PAN tests for routine medico-legal purposes, but under certain circumstances and with the essential reservation that nystagmography behind closed eyelids is used, it can be a complement to blood and urine alcohol analysis.

Goldberg, 1964) In these latter studies a quantitative factor—the degree of intoxication—was very marked As anticipated, a similar interaction between the two phases of PAN with their reversed beating directions was also found in this investigation

In the present experiments with multiple alcohol intake changes of various kinds in the course of the blood alcohol curves were observed All nystagmus observations in this investigation were correlated with the blood alcohol curves this close analysis of the material allowed the following conclusions

(1) The latency of PAN I depends on the rate of the initial blood alcohol rise. If the absorption of alcohol is very slow and consequently the increase in blood alcohol is also slow the latency time for PAN I may be as long as 2 hours.

In such experiments PAN I also appears at blood alcohol concentrations as low as 0 1 per mille. If on the other hand, the usual means of absorption is eliminated by injecting alcohol, the latency time can be reduced to $8^1/_2$–10 minutes.

(2) A *rising* blood alcohol induces a PAN I whose duration covers that period of time in which the blood alcohol is increasing, the subsequent blood alcohol maximum and at least 2 hours into the descending part of the curve Even such a low increase as 0 1–0.2 per mille over several hours causes a PAN I independent of where in the blood alcohol curve this rise occurs.

(3) A *falling* blood alcohol induces a PAN II after a latency time of at least 3 hours after the change-over from an ascending to a descending blood alcohol curve

(4) PAN II always lasted for several hours after the blood alcohol had returned to zero. The long duration of PAN II in the last group of experiments (up to 440 ml whisky over a period of $10^1/_2$ hours) confirms earlier observations that the duration of PAN II is dependent on the degree of intoxication even when the doses are spread out over such a long period!

(5) The *degree of intoxication* has marked influence on the intensity of PAN I This is valid not only for a primary PAN I but also for a secondary PAN II as shown especially in repeated two-dose experiments in the same test subject.

(6) Alcohol-induced positional nystagmus, whether PAN I or PAN II will always interact with each other when, as a result of repeated doses of alcohol, they are timed to coincide. This timing will depend on repetition of a rising and falling blood alcohol in the same blood alcohol curve On the basis of the resulting PAN the time schedule obtained in our single dose experiments was proved valid in this investigation also

(7) The resulting nystagmus phenomena will always be the algebraic sum of the beating direction and intensity of the two simultaneously present PAN at any given time point. Hence the parallelism with the interaction and resulting nystagmus described in the introduction between spontaneous vestibular nystagmus following labyrinthine destruction and PAN

These conclusions may be of value from some practical clinical or medico-legal aspects.

Blood alcohol concentrations as low as 0.1 per mille cause a positional nystagmus with an intensity and a beating direction what in clinical neuro-otological practice may lead to suspicion of severe neurological disturbances, particularly in the posterior fossa. Even rather moderate alcoholic intoxications, which may be easily overlooked, can be clinically misleading. Repetition of the tests—obviously without alcohol intake—after a few hours will answer this question Frenzel (1939) gave an example of the clinical errors that may result from PAN and this seems worth pointing out once more

The presence of both AON and a PAN I or II should indicate a blood alcohol concentration above 0 8 per mille In the clinic this should not present difficulties in differential diagnosis, but from a medico-legal aspect it may be of value

The presence of PAN I may show that alcohol must have been consumed within the last 4 hours. A PAN II on the other hand usually indicates that several hours have elapsed since

the last drink. Last but not least, the intermediate period reduces the possibilities of using PAN tests for routine medico-legal purposes, but under certain circumstances and with the essential reservation that nystagmography behind closed eyelids is used, it can be a complement to blood and urine alcohol analyses.

labyrinths. In all cases, testing sessions started 30 *minutes* after intramuscular injection of amphetamine sulfate (1 mg/kg of body weight) which was given to obtain reliable and stable levels of alertness. Stimulation was carried out under binocular or monocular conditions. In the latter case, an opaque sclerocorneal contact occluder was utilized in order not to interfere with the eye movements. In some experiments, the position of the monkey in space was varied by tilting in the frontal plane (roll angles) and/or placing the animal in the prone and supine positions (pitch angles).

The techniques for stimulation and recording have been described in detail in the earlier publications. In short, O.K.N. was induced by moving luminous stripes on a rear projection screen. The chosen stimulus parameters were a period of 64° at the center of the screen with a light/dark ratio of 1:9, four such periods being present on the screen at any one time. Stimulus temporal frequencies varied from 0.03 to 32 Hz and the *mean luminance of the light bars measured* from 0.82 log ftL to 7.73 log ftL. F.I.N. was elicited with a Grass PS2 photostimulator. The flicker frequency varied from 1 to 35 Hz; the flash duration was approximately 10 μsec at a luminous intensity of 3.87 × 10^{5} candles. Recording of eye movements was made with conventional AC electro-oculography. The method which has been described in detail in previous communications (Pasik et al., 1971; Pasik et al., 1973), allowed the identification of 8 vectors of rapid eye movements with respect to the head, namely upward, downward, to the right, to the left, and the four intermediate obliques.

The surgical techniques involved the section of the optic chiasm in the midsagittal plane (Pasik & Pasik, 1972) and/or the destruction of the labyrinths and section of the 8th nerves (Pasik & Pasik, 1973).

RESULTS AND DISCUSSION

Similarities between O.K.N. and F.I.N.

The characteristics common to both phenomena are summarized in Table I. Under proper conditions of alertness, O.K.N. and F.I.N. are reliably elicited responses which, after a variable build up period, are maintained during the entire duration of the stimulus (Fig. 1). Apparently there is no habituation for these phenomena as opposed to the well known decrease of vestibularly-induced nystagmus over time (Crampton, 1964). In fact, the characteristics of O.K.N. and F.I.N. remain the same over prolonged periods of stimulation and after repeated daily sessions utilizing the same stimulus parameters. After cessation of the stimulus, both responses persist for a variable time depending upon the quality of the nystagmus during stimulation (Krieger & Bender, 1956; Pasik et al., 1970). These optokinetic afternystagmus (O.K.A.N.) and flicker-induced afternystagmus (F.I.A.N.) occur in the same direction of the preceding responses and show a progressive decrease in the frequency (Fig. 1). Eventually they are replaced by either random movements or a period of nystagmus in the opposite direction, i.e. an after-after response. O.K.A.N. and F.I.A.N. appear only if the cessation of the stimulus coincides with total darkness, and are immediately interrupted by illuminating the testing chamber. It should be emphasized that the after-after response, i.e. the inversion of the direction of nystagmus, is much more prominent in F.I.N. than in O.K.N.

Stimulus-response relationships have been studied for both phenomena (Pasik et al., 1970; Valciukas et al., 1973). The influence of stimulus temporal frequency (F_s), and therefore its velocity upon nystagmus frequency (F) is of a similar nature in O.K.N. and F.I.N. The general function describing this relationship is of the

Acta Otolaryngol Suppl 330 30–37 1975

A COMPARISON BETWEEN TWO TYPES OF VISUALLY EVOKED NYSTAGMUS IN THE MONKEY[1]

Pedro Pasik and Tauba Pasik

From the Department of Neurology Mount Sinai School of Medicine of The City University of New York N Y USA

Abstract Similarities between optokinetic nystagmus (O K N) and flicker-induced nystagmus (F I N) include response buildup and occurrence during the entire period of stimulation absence of habituation after nystagmus in the same direction occasional after-after nystagmus to the opposite side frequency spectrum, peak frequency and existence of lower and upper frequency thresholds. Phenomena are different in that for O K N the stimulus is in motion binocular and monocular stimulation are effective direction is determined by direction of motion unidirectionality is absent there is minimal influence of background illumination posture, labyrinthine receptors, and section of crossed optic fibers. For F I N the stimulus is stationary the response is elicited only by monocular stimulation the direction is determined by the stimulated eye there is exclusive unidirectionality it is abolished by background illumination, optic chiasm section and bilateral labyrinthectomy it is strongly influenced by posture. This comparison suggests that O K N and F I N are separate responses and that the effective stimulus for F I N may activate selectively the crossed optic fibers.

It has long been known that nystagmus of the eyes can be elicited by visual stimuli Traditionally this oculomotor response has been termed optokinetic nystagmus (O K N) since the proper stimulus is the motion of the optic targets. The quick phase is in the direction opposite to the stimulus movement This was the only known type of optically evoked nystagmus until 1965 when Costin Chaimovitz and Bergmann described a new kind of nystagmus elicited in the rabbit by stationary repetitive flashes of light (flicker) delivered to one eye In this case the quick phase was toward the side of the stimulated eye The observations were extended by Pasik et al (1970) who reproduced the phenomenon in the monkey A similar effect has since been observed in the cat (unpublished observations), but apparently cannot be obtained in man (Keane 1972) To date there is no clear explanation for flicker induced nystagmus (F I N) Several possible mechanisms have been offered recently (Pasik et al 1973) One possibility is that flicker stimulation evokes the perception of apparent motion which in turn could elicit an oculomotor response of a similar nature to O K N In view of this contingency it was considered useful to compare the two phenomena, O K N and F I N both in their absolute characteristics, and in the effects of manipulating the stimulus parameters, the posture of the experimental animal as well as the influence of the relative integrity of the visual and vestibular systems These are the purposes of the present communication

MATERIAL AND METHODS

The comparison is based on the results of previous studies on O K N and F I N (Pasik et al 1970 Valciukas et al., 1973 Valciukas, 1972 Pasik et al., 1973 T Pasik & P Pasik 1964 1972) to which certain preliminary new data have been added In total 48 monkeys (*Macaca mulatta*) were examined and tested either in the normal state or after interference with pregeniculate visual pathways and/or destruction of the

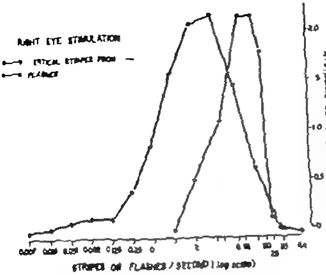

Fig. 4. Frequency spectra of O.K.N. and F.I.N. in normal monkey. Both curves derive from data of the same animal. Note the similarity of the positive acceleration portions which are practically parallel and show a linear increase of response frequency with the logarithm of stimulus temporal frequency. Peak responses are the same. The decline portions are somewhat different in this case. However, group data showed better agreement (Pasik et al., 1970; Valciukas et al., 1973).

upper limit above which the response ceases to occur. According to the available data the upper threshold would be between 20 and 25 Hz at the tested luminance level.

Differences between O.K.N. and F.I.N.

The features on which O.K.N. and F.I.N. differ are listed in Table II. A first consideration should be given to the characteristics of the stimuli which elicit one and the other type of nystagmus. It is clear that O.K.N. is evoked by successive moving stimuli traversing the visual field. Although there is a tendency to equate the slow phase of nystagmus with smooth pursuit eye movements and the fast phase with the saccades, it appears that the nystagmic beat is a unit which

Table II. *Differences between O.K.N. and F.I.N.*

Characteristics	O.K.N.	F.I.N.
1. Stimulus	In motion	Stationary
2. Binocular or monocular stimulation	Both	Monocular only
3. Determinants of direction	Direction of motion	Stimulated eye
4. Unidirectionality	Absent	Present
5. Effect of optic chiasm section	None	Abolition
6. Background illumination	Minor influence	Suppression
7. Influence of posture	Minor (?)	Major
8. Effect of bilateral labyrinthectomy	Minor	Abolition

is difficult to uncouple. In fact, lesions of the central nervous system affecting conjugate gaze in a particular direction interfere with all kinds of eye movements in that direction, namely smooth pursuit, saccades and optokinetic nystagmus as named by the direction of the quick phase (Bender, 1969). The stimulus for F.I.N. is a flickering light which is stationary. There is no physical component of real motion in it, and a question that comes up is whether this kind of stimulus may be eliciting the perception of apparent motion, either through hallucinatory experiences characteristic of "stroboscopic patterns" (Smythies, 1959), or through a type of phi-phenomenon evoked by initial random saccades which would place the stationary source of light at successive spots on the retina (Pasik et al., 1970). Further experiments are needed to test this hypothesis.

Another major difference between O.K.N. and F.I.N. is that the former may be obtained by stimulation of both eyes simultaneously or of each eye at a time. Contrariwise, F.I.N. can only be elicited under monocular stimulation conditions (Costin et al., 1965; Pasik et al., 1970), except on rare occasions when binocular stimulation has been observed to evoke a response of different characteristics (see below). The determinants of the direction of nystagmus, traditionally named by the quick phase, is also

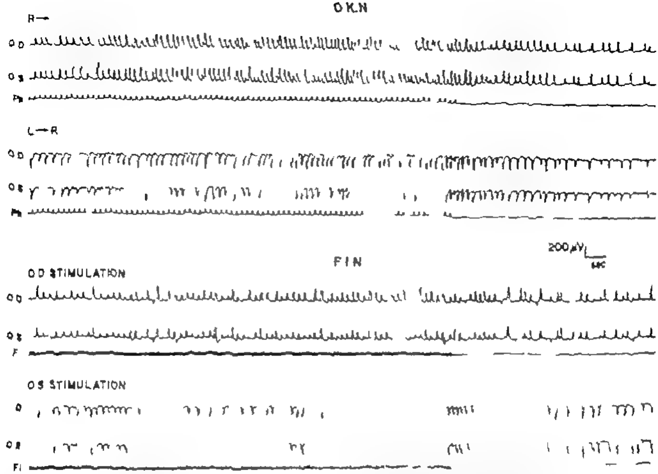

Fig. 1 Electro-oculograms of O.K.N, O.K.A.N., F.I.N and F.I.A.N in normal monkey. *R→L* and *L→R* indicate movement of optokinetic stimuli from right to left, and left to right respectively. *O.D.* right eye. *O.S.*, left eye. *Ph.*, photocell monitoring (2 Hz). *Fl.*, flicker monitoring (10 Hz). Note the initial build up of both responses, the similar peak frequencies, the occurrence of after nystagmus after cessation of stimulation, and its progressive decrease.

type $F = F\ (a + b \log F)$. Fig. 2 depicts the findings. It is clear that in both cases nystagmus frequency increases linearly with the logarithm of stimulus frequency to a peak and declines thereafter. The shift of the curves along the abscissa could well be due to the differences in the luminance of the stimuli, a factor which has been shown to modify the frequency spectrum of O.K.N. by its influence on the constant a (Valciukas et al. 1973). Comparable studies of the effect of luminance on F.I.N. are not available. It is interesting to note that the mean peak frequency of both O.K.N. and F.I.N. at least at the stimulus values chosen, are also similar and of the order of 2.0–2.5 nystagmic beats/second. These peak responses are elicited by stimulus temporal frequencies of about 4 Hz for O.K.N. and 10–15 Hz for F.I.N. This difference may again reflect the different luminance levels used. The tails of both curves presumably represent the regions where lower and upper thresholds are expected. Again there is a difference in the stimulus values eliciting lower threshold responses, which are of the order of 0.2 Hz for O.K.N. (Valciukas, 1972) and 2 Hz for F.I.N. (Pasik et al. 1970). The frequency of the response at threshold, however, is similar for both phenomena and of the order of 0.3 nystagmic beats/sec. The upper frequency thresholds have been shown to be strongly influenced by the luminance level in O.K.N. (Valciukas, 1972). Although no comparison can be made since these determinations are lacking for F.I.N., it is clear from the curves that F.I.N. has also an

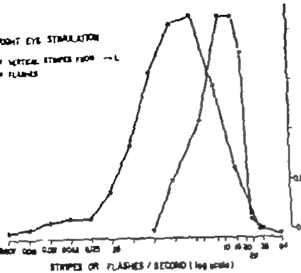

Fig. 2. Frequency spectra of O.K.N. and F.I.N. in normal monkey. Both curves derive from data of the same animal. Peak responses are the same. The decline portions are somewhat different in this case. However, group data showed a better agreement (Pasik et al., 1970; Valciukas et al., 1973).

upper limit above which the response ceases to occur. According to the available data the upper threshold would be between 20 and 25 Hz at the tested luminance level.

Differences between O.K.N. and F.I.N.

The features on which O.K.N. and F.I.N. differ are listed in Table II. A first consideration should be given to the characteristics of the stimuli which elicit one and the other type of nystagmus. It is clear that O.K.N. is evoked by successive moving stimuli traversing the visual field. Although there is a tendency to equate the slow phase of nystagmus with smooth pursuit eye movements and the fast phase with the saccades, it appears that the nystagmic beat is a unit which is difficult to uncouple. In fact, lesions of the central nervous system affecting conjugate gaze in a particular direction interfere with all kinds of eye movements in that direction, namely smooth pursuit, saccades and optokinetic nystagmus as named by the direction of the quick phase (Bender, 1969). The stimulus for F.I.N. is a flickering light which is stationary. There is no physical component of real motion in it, and a question that comes up is whether this kind of stimulus may be eliciting the perception of apparent motion, either through hallucinatory experiences characteristic of "stroboscopic patterns" (Smythies, 1959), or through a type of phi-phenomenon evoked by initial random saccades which would place the stationary source of light at successive spots on the retina (Pasik et al., 1970). Further experiments are needed to test this hypothesis.

Table II. *Differences between O.K.N. and F.I.N.*

Characteristics	O.K.N.	F.I.N.
1. Stimulus	In motion	Stationary
2. Binocular or monocular stimulation	Both	Monocular only
3. Determinants of direction	Direction of motion	Stimulated eye
4. Unidirectionality	Absent	Present
5. Effect of optic chiasm section	None	Abolition
6. Background illumination	Minor influence	Suppression
7. Influence of posture	Minor (?)	Major
8. Effect of bilateral labyrinthectomy	Minor	Abolition

Another major difference between O.K.N. and F.I.N. is that the former may be obtained by stimulation of both eyes simultaneously or of each eye at a time. Contrariwise, F.I.N. can only be elicited under monocular stimulation conditions (Costin et al., 1965; Pasik et al., 1970), except on rare occasions when binocular stimulation has been observed to evoke a response of different characteristics (see below). The determinants of the direction of nystagmus, traditionally named by the quick phase, is also

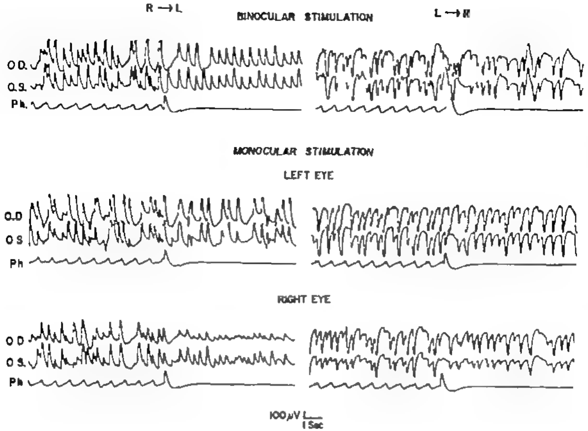

Fig 3 Electro-oculograms of O K.N and O K.A.N. under binocular and monocular stimulation in the normal monkey Notations as in Fig. 1 Note the similarity of responses and afterresponses under both testing conditions. Contrariwise, F I N is obtained only on monocular stimulation (see text).

different. In O K N it is given by the direction of the stimulus motion which is opposite to that of the response. The direction of F I N is determined by the stimulated eye the quick phase being to the right on stimulation of the right eye and to the left on stimulation of the left eye This is a constant feature of F.I N under any condition of testing. Although the quick phase may have an oblique component it has always a horizontal vector to the side of the stimulated eye. On the rare occasions when F I N was elicited also by binocular stimulation the nystagmus had a vertical character being usually upwards when the animal was tested in the erect position

Fukuda & Tokita (1957) were first to report the characteristic unidirectionality of O K N in lower mammals with almost totally crossed optic nerves, a finding previously noticed by other authors in birds (Huizinga & Meulen, 1951) It was found that rabbits and guinea pigs exhibited a similar O K N to the right and to the left under binocular stimulation whereas monocular stimulation evoked a *strong response* only when motion was toward the covered eye resulting in a nystagmus in the direction of the uncovered eye For example there was strong nystagmus to the right on stimulation of the right eye only when stripes moved from the right to the left. When the stripes moved from the left to the right the response was either absent or considerably weaker These authors pointed out that unidirectionality was not present in man and attributed this characteristic to the fact that approximately only 50 of the optic fibers cross at the optic chiasm in humans. Fig. 3 shows similar findings in the monkey which also carries about the same proportion of crossed/uncrossed fibers in the chiasm It can be seen that indeed there is no difference between O K N elicited under binocular or monocular conditions. On the other hand, F I N

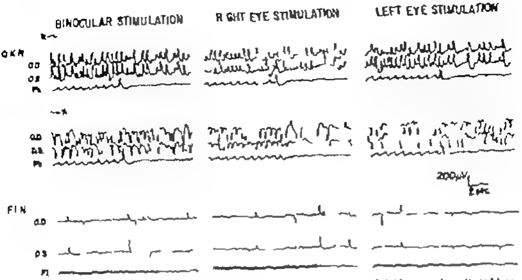

Fig. 4. Electro-oculograms from monkeys with midsagittal section of the optic chiasm during and after optokinetic or flicker stimulation. Notations as in Fig. 1. It is evident that severing all crossed optic fibers did not change the O.K.N. and O.K.A.N. even when elicited by monocular stimulation, whereas F.I.N. could not be obtained under any testing condition after the section.

shows a remarkable unidirectionality in the monkey. It can only be obtained to the right on stimulation of the right eye, and to the left on stimulation of the left eye. It should be recalled that F.I.N. was first discovered in the rabbit (Costin et al., 1965) and the question was raised whether the phenomenon could be due to the exclusive stimulation of one optic pathway since this animal has an almost total decussation of the optic nerves. It appears that the monkey reacts with respect to F.I.N. as if using only its crossed optic fibers.

The effect of midsagittal section of the optic chiasm in the monkey is relevant to this discussion. In fact, the discovery of unidirectionality of O.K.N. in lower mammals (Fukuda & Tokita, 1957) inspired us to attempt to reproduce it in reverse in the monkey by eliminating the crossed fibers. The hypothesis was that by creating a preparation with only uncrossed fibers, the unidirectionality of O.K.N. would become evident, but in the reverse direction to that shown by animals with totally crossed optic fibers. The results, originally reported in 1964 (T. Pasik & P. Pasik, 1964), are illustrated in Fig. 4, top. It is apparent that there was no difference between O.K.N. elicited under binocular and monocular conditions in monkeys with chiasm section. No unidirectionality was thus created. We further demonstrated that this was due to the fact that, although the crossed fibers were sectioned, the hemisphere ipsilateral to the stimulated eye made available visual information to the opposite hemisphere through the corpus callosum and perhaps through other brain commissures as well (Pasik & Pasik, 1972). Findings were dramatically different with respect to F.I.N. This phenomenon, which as shown above exhibits an exclusive unidirectionality with respect to the stimulated eye, was totally abolished by midsagittal section of the optic chiasm and did not recover for the entire 3 month follow up period (Fig. 4, bottom).

The influence of background light is considerably different for O.K.N. and F.I.N. The optokinetic response may be evoked in the presence of some levels of illumination provided there is enough contrast in the stimulus pattern. The flicker-induced response requires total darkness and it immediately ceases upon introduction of illumination in the testing chamber. Moreover F.I.N. is also abolished by stimulation of the

covered eye with a constant steady light (Costín et al. 1965).

It is well known that there is marked interaction between the visual and vestibular systems (Fukuda et al. 1957, Fukuda, 1959). Prompted by the latter studies, we attempted to investigate the influence of posture upon O.K.N. and F.I.N. Preliminary results on O.K.N. have shown no major differences in the response when elicited with the monkey in the erect position or in the right lateral or left lateral posture, using in every case stimuli moving to the right or to the left of the animal irrespective of its position. These results are apparently different than those obtained by Kurata (1958) who found such an influence present in birds. Although further studies are necessary to confirm our preliminary results, the data are still useful in terms of revealing a marked contrast with the influence of posture upon the direction and frequency of F.I.N. We have recently shown (Pasik et al. 1973) that the prevailing vector of F.I.N. has a component to the side of the stimulated eye in all positions tested, but there is also an oblique component which varies sinusoidally with the angle of tilt in the frontal plane (roll angle) and it is minimally influenced by tilts in the sagittal plane (pitch angle). Moreover, the direction of nystagmus at every tilt is strictly opposite when elicited by right or left eye stimulation. There are also changes in nystagmus frequency with tilts in the frontal plane which were similar for both eyes, being maximal in the upside-down and minimal in the lateral position. Since the influence of posture on F.I.N. could most possible reflect the function of the otolith organ, a first attempt was made to eliminate this influence by destruction of the labyrinths. The results were indeed unexpected: F.I.N. could not be elicited after bilateral labyrinthectomy in otherwise intact monkeys. It has been noted that although there are some O.K.N. changes in labyrinthectomized monkeys, the maximal effect is exerted on optokinetic afternystagmus (O.K.A.N.) which is permanently abolished by this lesion (Uemura & Cohen 1973). It appears therefore that the vestibular receptor organs are essential for F.I.N. and O.K.A.N. The meaning of this latter similarity is obscure.

COMMENTS

The preceding comparison revealed some similarities and major differences between O.K.N. and F.I.N. The similarities can be indicative of a common mode of reaction of the oculomotor system to repetitive visual stimuli whether they are in time and space (O.K.N.) or just in time (F.I.N.). The differences, however, suggest that the two responses are separate phenomena and consequently cast doubts on the interpretation that F.I.N. is merely a case of O.K.N. elicited by the perception of apparent motion. In earlier studies on oculomotor pathways we have shown that an adequate visual input must reach a given side of the brain to initiate an oculomotor output to the opposite side (P. Pasik & T. Pasik, 1964, T. Pasik & P. Pasik 1964). This conclusion applied to both conjugate gaze and O.K.N. Moreover, oculomotor output for vestibular nystagmus followed the same pattern. There is no reason to believe that F.I.N. behaves differently in this respect. Since F.I.N. is only elicited by monocular stimulation and occurs exclusively in the direction of the stimulated eye, it appears that the effective stimulus activates predominantly the phylogenetically older crossed optic fibers. This hypothesis is supported by the abolition of F.I.N. after chiasm section and by current findings in our laboratory showing that monkeys with one optic tract severed exhibit F.I.N. only when stimulation is delivered to the eye with preserved crossed fibers, i.e. the eye on the side of the lesion, and cannot be obtained from the other eye.

ZUSAMMENFASSUNG

Gleiche spezifische Eigenschaften zwischen optokinetischem Nystagmus (O.K.N.) und Nystagmus, ausgelöst durch Flicker (F.I.N.), bestehen in gradueller Steigerung des Nystagmus und Fortbestehen während der ganzen Stimulierungsperiode; Abwesenheit von Gewöhnungseffekt; Nach-Nystagmus in die gleiche Richtung; dem gelegentlichen Auftreten von Nach-Nach-Nystagmus in die entgegengesetzte Richtung; dem gleichen Spektrum.

das heisst der gleichen Höhenfrequenz und dem Bestehen von demselben *niedrigen und hohen* Frequenzgrenzen. Folgende Unterschiede bestehen für den O.k.N., der Stimulusreiz ist von der Bewegung abhängig; binokulare und monokulare Stimulierungen sind wirksam, die Nystagmusrichtung wird durch die Richtung der Bewegung diktiert, Abwesenheit des einseitigen Nystagmus, dem *Bestehen* von nur *geringfügigem* Einfluss von Hintergrundbeleuchtung, von Position, Labyrinthrezeptoren und von dem Bereich der getrennten optischen Nerven. Der Stimulus *für den F.I.N.* ist stationär, er wird nur durch monokulare Stimulierung ausgelöst; die Nystagmusrichtung wird durch die Stimulierung des Auges diktiert, dem Bestehen von ausschliesslich einer Nystagmusrichtung; er wird aufgehoben durch Hintergrundbeleuchtung, durch Durchtrennung des optischen Chiasmas und durch bilaterale Labyrinthektomie, und er ist stark von der Position des Stimulus beeinflusst. Diese Vergleichsuntersuchungen deuten an, dass der O.K.N. und der F.I.N. unterschiedliche neurologische Reaktionen darstellen und dass der auslösende Stimulus für den *F.I.N.* vorwiegend auf dem Wege der gekreuzten optischen Fasern wirksam ist.

RÉSUMÉ

Les ressemblances entre le nystagmus optocinétique (O.K.N.) et le nystagmus induit par la scintillation (F.I.N.) sont: réponse en accroissement et occurrence pendant la période suivie de stimulation, manque d'habituation, après-nystagmus dans la même direction; occasionnellement après-après-nystagmus vers le côté opposé; spectre de fréquence, sommet de fréquence et existence de seuils de fréquence inférieur et supérieur. Les épiphénomènes sont différents pour que pour O.K.N. le stimulus est en mouvement; les stimulations monoculaires et binoculaires sont efficaces, la direction est déterminée par la direction du mouvement, l'unidirectionnalité est absente; l'influence de l'illumination de fond, de la posture, des récepteurs labyrinthiques et de la coupe du chiasma optique, sont mineures. Pour F.I.N., le stimulus est stationnaire, la réponse est provoquée seulement par la stimulation monoculaire; la direction est déterminée par l'œil stimulé; l'unidirectionnalité est totale; la réponse disparaît si le fond est éclairé, le chiasma est sectionné, ou s'il y a une labyrinthectomie bilatérale. La posture a une forte influence. Cette comparaison suggère que l'O.K.N. et le F.I.N. sont des réponses différentes et que le stimulus efficace pour le F.I.N. peut activer avec prédominance les fibres optiques croisées.

LES SYNDROMES VESTIBULAIRES CENTRAUX

G F Greiner C Conraux et M Collard

Strasbourg France

La notion de syndrome vestibulaire central s est peu à peu dégagée de l étude de l appareil vestibulaire en général et des troubles de l équilibration

Certes, le rôle du labyrinthe dans l équilibre est établi depuis les observations de Darwin en 1801 qui avait déjà noté l illusion de contre-rotation ressentie à l arrêt d un mouvement de rotation qu il effectuait autour de sa canne celles de Purkinje en 1820 de Flourens en 1824 de Ménière sur le plan clinique en 1861 Ce n est qu à la fin du siècle dernier que le nystagmus fût rattaché à une éventuelle lésion labyrinthique jusqu alors il était considéré comme un phénomène d origine oculaire (nystagmus des mineurs)

Si l essentiel de nos connaissances sur l appareil vestibulaire périphérique était donc acquis au début de ce siècle à la suite des études de Mach Bárány Buys, Hennebert, la notion de syndrome vestibulaire central ne s est progressivement individualisée qu à partir des travaux de neurologistes tels que Babinski André Thomas Van Gehuchten et surtout de Barre à partir de 1920 à Strasbourg Il eut le grand mérite d y consacrer la majeure partie de son activité et d élaborer une véritable séméiologie vestibulaire centrale. Ses élèves ont poursuivi son travail multipliant les observations cliniques, dégageant la symptomatologie vestibulaire de la symptomatologie cérébelleuse confrontant les données de la pathologie aux travaux anatomiques et physiologiques.

La mise au point depuis une quinzaine d années de l électronystagmographie clinique et de nouvelles techniques d examen et de stimulations physiologiques et non traumatisantes a abouti à l élaboration d une véritable vestibulométrie c est à dire à la possibilité de mesures précises des réponses vestibulaires à des stimulations connues, reproductibles et adaptées.

C'est à partir des documents d une telle confrontation otoneurologique que nous essayerons de cerner la notion de syndrome vestibulaire central et d en préciser les différents aspects.

I LE SYNDROME VESTIBULAIRE CENTRAL

A *La notion de syndrome vestibulaire central* s établit à partir des résultats de l expérimentation et des constatations cliniques.

En résumant très schématiquement les *données anatomiques et physiologiques* on peut dire que jusqu au niveau des noyaux vestibulaires primaires bulboprotubérantiels les expériences de stimulation et de destruction sont très comparables à celles faites sur le récepteur ou sur le nerf vestibulaire sitôt que l on s éloigne de ce niveau, les interférences deviennent extraordinairement complexes et le fonctionnement de l appareil vestibulaire se trouve intégré à trois systèmes différents bien que complémentaires

— l oculomotricité et ses connexions elle est le support du nystagmus,
— la motricité axiale et segmentaire u point de départ médullaire qui est l aboutissement du système *vestibulo-spinal*
— l activité psychique consciente à travers laquelle s exprime le trouble subjectif (ou vertige) qui peut résulter des lésions vestibulaires

C'est à dire que la perturbation de l'un ou de plusieurs de ces trois grands systèmes pourra *simuler* un élément du syndrome vestibulaire, mais pourra aussi *modifier l'expression* de celui-ci. Les exemples en sont nombreux en pratique

Ainsi l'existence d'un nystagmus spontané ne témoigne pas nécessairement d'une lésion vestibulaire d'autre part un nystagmus d'origine vestibulaire verra ses caractéristiques modifiées *dans le cas d'atteinte associée de l'appareil oculo-moteur* (parésie, ophtalmoplégie).

Ainsi également, certaines atteintes de l'équilibre axial sont sans rapport avec une lésion vestibulaire d'autre part, un syndrome vestibulo-spinal peut être difficile à caractériser en cas de troubles associés des cordons médullaires.

Ainsi enfin, *il existe* des troubles *qualifiés de* vertiges sans atteinte connue du système vestibulaire d'autre part, certains vertiges d'origine vestibulaire sont d'expression clinique très atypique du fait de lésions cérébrales ou de troubles psychiques.

Cela permet de comprendre que *la définition et les limites du syndrome vestibulaire central* sont extrêmement floues et difficiles à établir. Une conception rigoureuse exigerait que, pour parler de syndrome vestibulaire il y ait à la fois des troubles subjectifs vertigineux, un syndrome clinique comportant nystagmus et déviations et des *altérations des réponses vestibulaires instrumentales*.

A l'inverse, une conception élargie va jusqu'à reconnaître le caractère vestibulaire à l'un quelconque de ces éléments, même isolé impression vertigineuse, ou nystagmus, ou déviations, ou anomalie de la réflectivité vestibulaire par exemple

Nous pensons que la notion et les limites des syndromes vestibulaires centraux ne peuvent être définis du point de vue anatomique, mais reposent sur une conception physiopathologique

A *l'état normal*, l'appareil vestibulaire fonctionne de manière *purement inconsciente donc* la prise de conscience d'une sensation de vertige témoignera soit d'une stimulation anormale, extraphysiologique (mal de mer par exemple), soit d'altérations propres à l'appareil vestibulaire. La notion de vertige nécessitera donc un examen clinique et des investigations vestibulométriques pour rechercher de telles altérations. L'absence de troubles subjectifs ne témoignera cependant pas d'absence de lésion vestibulaire et ne permettra donc jamais d'éliminer une atteinte de cet appareil.

De même, les *stimulations* vestibulaires *aboutissent à la fois* aux motoneurones oculaires et aux motoneurones spinaux il y aura nystagmus et déviations l'absence de l'un ou de l'autre signifie perturbation dans la transmission du message vestibulaire et devra être expliquée par d'autres altérations neurologiques pour permettre de reconnaître une signification « vestibulaire » *à un syndrome* incomplet ou à un syndrome dysharmonieux.

C'est donc par son intégration aux données du bilan vestibulométrique et de l'examen neurologique qu'un symptome clinique pourra être rattaché à une altération vestibulaire centrale.

B *Séméiologie clinique*

Elle est bien classique et sera simplement résumée.

Les troubles subjectifs sont faits de vertiges ou de sensations vertigineuses peu intenses, mal systématisées, mal définies par le sujet. Il faut mettre à part les grands vertiges rotatoires par lésion des noyaux vestibulaires primaires ceux *du syndrome de Wallenberg* et de certaines formes de sclérose en plaques, *qui rappellent les* vertiges du syndrome vestibulaire périphérique, probablement parce qu'ils sont effectivement dus à une lésion du premier neurone ou de la première jonction neuronale.

En dehors de ces cas, le vertige d'origine centrale *est fait le plus souvent d'une impression* de déséquilibre, d'une sensation d'insécurité, d'ébriété, *volontiers déclenchée ou provoquée* par certaines positions de la tête et du corps, de brève durée, peu gênante, mais contraignante par sa répétition pendant des semaines ou des mois. Ces troubles ne s'accompagnent pas souvent *de manifestations végétatives* sinon quelques rares nausées et *sont habituellement améliorés* par la fermeture des yeux. Ils *ne sont* en

La notion de syndrome vestibulaire central s est peu à peu dégagée de l étude de l appareil vesti bulaire en général et des troubles de l équili bration

Certes, le rôle du labyrinthe dans l équilibre est établi depuis les observations de Darwin en 1801 qui avait déjà noté l illusion de contre-rotation ressentie à l arrêt d un mouvement de rotation qu il effectuait autour de sa canne celles de Purkinje en 1820 de Flourens en 1824 de Ménière sur le plan clinique en 1861 Ce n est qu à la fin du siècle dernier que le nystagmus fût rattaché à une éventuelle lésion labyrin thique jusqu alors il était considéré comme un phénomène d origine oculaire (nystagmus des mineurs)

Si l essentiel de nos connaissances sur l appa reil vestibulaire périphérique était donc acquis au début de ce siècle à la suite des études de Mach Bárány Buys, Hennebert la notion de syndrome vestibulaire central ne s est progressivement individualisée qu à partir des travaux de neurologistes tels que Babinski André Thomas, Van Gehuchten et surtout de Barre à partir de 1920 à Strasbourg. Il eut le grand mérite d y consacrer la majeure partie de son activité et d élaborer une véritable séméiologie vestibulaire centrale Ses élèves ont poursuivi son travail, multipliant les observations cliniques, dégageant la symptomatologie vestibulaire de la symptoma tologie cérébelleuse, confrontant les données de la pathologie aux travaux anatomiques et physiologiques.

La mise au point depuis une quinzaine d années de l électronystagmographie clinique et de nouvelles techniques d examen et de stimulations physiologiques et non traumatisantes a abouti à l élaboration d une véritable vestibulométrie c est à dire à la possibilité de mesures précises des réponses vestibulaires à des stimu lations connues, reproductibles et adaptées.

C'est à partir des documents d une telle confrontation otoneurologique que nous essayerons de cerner la notion de syndrome vestibulaire central et d en préciser les différents aspects.

I LE SYNDROME VESTIBULAIRE CENTRAL

A *La notion de syndrome vestibulaire central* s établit à partir des résultats de l'expérimenta tion et des constatations cliniques.

En résumant très schématiquement les *données anatomiques et physiologiques* on peut dire que jusqu au niveau des noyaux vestibulaires primaires bulboprotubérantiels, les expériences de stimula tion et de destruction sont très comparables à celles faites sur le récepteur ou sur le nerf vestibulaire sitôt que l on s éloigne de ce niveau, les interférences deviennent extraordinairement complexes et le fonctionnement de l appareil vestibulaire se trouve intégré à trois systèmes différents bien que complémentaires

— l'oculomotricité et ses connexions elle est le support du nystagmus,
— la motricité axiale et segmentaire à point de départ médullaire qui est l aboutissement du système vestibulo-spinal
— l activité psychique consciente à travers la quelle s exprime le trouble subjectif (ou vertige) qui peut résulter des lésions vestibulaires

C'est à dire que la perturbation de l'un ou de plusieurs de ces trois grands systèmes pourra *simuler* un élément du syndrome vestibulaire, mais pourra aussi *modifier l'expression* de celui-ci. Les exemples en sont nombreux en pratique.

Ainsi l'existence d'un nystagmus spontané ne témoigne pas nécessairement d'une lésion vestibulaire; d'autre part un nystagmus d'origine vestibulaire verra ses caractéristiques modifiées dans le cas d'atteinte associée de l'appareil oculomoteur (parésie, ophtalmoplégie ...).

Ainsi également, certaines atteintes de l'équilibre axial sont sans rapport avec une lésion vestibulaire; d'autre part, un syndrome vestibulo-spinal peut être difficile à caractériser en cas de troubles associés des cordons médullaires.

Ainsi enfin, il existe des troubles qualifiés de vertiges sans atteinte connue du système vestibulaire; d'autre part, certains vertiges d'origine vestibulaire sont d'expression clinique très atypique du fait de lésions cérébrales ou de troubles psychiques.

Cela permet de comprendre que *la définition et les limites du syndrome vestibulaire central* sont extrêmement floues et difficiles à établir. Une conception rigoureuse exigerait que, pour parler de syndrome vestibulaire il y ait à la fois des troubles subjectifs vertigineux, un syndrome clinique comportant nystagmus et déviations et des altérations des réponses vestibulaires instrumentales.

A l'inverse, une conception élargie va jusqu'à reconnaître le caractère vestibulaire à l'un quelconque de ces éléments, même isolé: impression vertigineuse, ou nystagmus, ou déviations, ou anomalie de la réflectivité vestibulaire par exemple.

Nous pensons que la notion et les limites des syndromes vestibulaires centraux ne peuvent être définies du point de vue anatomique, mais reposent sur une conception physiopathologique.

A l'état normal, l'appareil vestibulaire fonctionne de manière purement inconsciente: donc la prise de conscience d'une *sensation* de vertige témoignera soit d'une stimulation anormale, extraphysiologique (mal de mer par exemple), soit d'altérations propres à l'appareil vestibulaire. La notion de vertige nécessitera donc un examen clinique et des investigations vestibulométriques pour rechercher de *telles altérations*. L'absence de troubles subjectifs ne témoignera cependant pas d'absence de lésion vestibulaire et ne permettra donc jamais d'éliminer une atteinte de cet appareil.

De même, les stimulations vestibulaires aboutissent à la fois aux motoneurones oculaires et aux motoneurones spinaux. Il y aura nystagmus et déviations: l'absence de l'un ou de l'autre signifie perturbation dans la transmission du message vestibulaire et devra être expliquée par d'autres altérations neurologiques pour permettre de reconnaître une signification « vestibulaire » à un syndrome *incomplet* ou à un syndrome dysharmonieux.

C'est donc par son intégration aux données du bilan vestibulométrique et de l'examen neurologique qu'un symptôme clinique pourra être rattaché à une altération vestibulaire centrale.

B. *Séméiologie clinique*

Elle est bien classique et sera simplement résumée.

Les troubles subjectifs sont faits de vertiges ou de sensations vertigineuses peu intenses, mal systématisées, mal définies par le sujet. Il faut mettre à part les grands vertiges rotatoires par lésion des noyaux vestibulaires primaires: ceux du syndrome de Wallenberg et de certaines formes de sclérose en plaques, qui rappellent les vertiges du syndrome vestibulaire périphérique, probablement parce qu'ils sont effectivement dus à une *lésion* du premier neurone ou de la première jonction neuronale.

En dehors de ces cas, le vertige d'origine centrale est fait le plus souvent d'une impression de déséquilibre, d'une sensation *d'insécurité*, d'ébriété, volontiers *déclenchée ou provoquée par certaines positions* de la tête et du corps, de *brève durée*, peu gênante, mais contraignante *par sa répétition* pendant des semaines ou des mois. *Ces troubles ne s'accompagnent pas souvent de manifestations* végétatives sinon quelques rares nausées et sont habituellement améliorés *par la fermeture* des yeux. Ils ne sont en

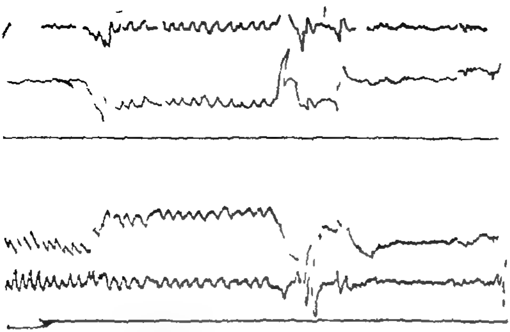

Fig 1 Nystagmus spontané de forme pendulaire d ori gine neurologique portant sur les 2 yeux dans le regard gauche (tracé du haut), dans le regard droit (tracé du bas).

général pas associés à des troubles auditifs latéralisés.

Les troubles subjectifs sont d autant plus importants que la lésion originelle s est installée brutalement que cette lésion est strictement unilatérale ou très asymétrique, que cette lésion est proche des noyaux vestibulaires primaires.

Les signes spontanés se manifestent en géné ral sous la forme d un syndrome vestibulaire dysharmonieux tel *que l a défini* Barré ou un syndrome parcellaire incomplet atypique

C *La séméiologie vestibulométrique* est d un apport souvent considérable pour le diagnostic topographique

S'il n existe que très rarement des signes pathognomoniques d une atteinte vestibulaire centrale certaines altérations cependant sont très évocatrices, et cette suspicion fait place à une quasi certitude lorsque plusieurs de ces signes sont retrouvés à l analyse du tracé nystagmographique

L étude du regard

— la forme du nystagmus n est en général pas caractéristique à l exception du nystagmus rotatoire pur , pratiquement toujours d origine bulbaire et du nystagmus pendulaire, d *origine neurologique ou oculaire* (Fig. 1 et 2)

— la nature du nystagmus. Un nystagmus multidirectionnel horizontal et vertical dans les différentes positions du regard est presque sûrement d origine neurologique (Fig. 3 et 4).

— la dissociation inter-oculaire du nystagmus. Un nystagmus *spontané* c est à dire dans le regard *direct* dissocié à prédominance monoculaire ou monoculaire pur (nystagmus ataxique de Harris) est toujours d origine centrale Il traduit une lésion de la bandelette longitudinale postérieure et se rencontre en particulier dans l ophtalmoplégie *internucléaire Par contre* la prédominance monoculaire légère sur l œil en abduction dans les regards externes n a que peu de valeur *localisatrice* (Fig. 5 et 6).

Les troubles de la réflectivité

— les altérations quantitatives. *L hyporéflectivité unilatérale est essentiellement* l apanage des

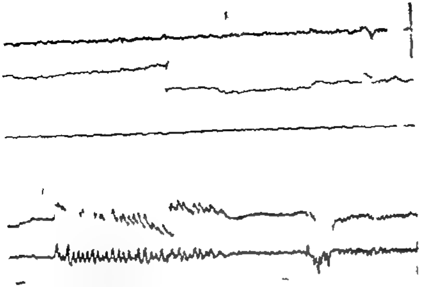

Fig. 2. Nystagmus spontané de forme pendulaire d'origine neurologique, vertical dans le regard vers le haut et vers le bas (tracé inférieur).

atteintes périphériques ou nucléaires. La compensation et le recrutement vestibulaires viennent en modifier plus ou moins les caractères sur le plan des réponses aux épreuves rotatoires, mettant ainsi en évidence les possibilités de régulation centrale dont ils permettent de tester le fonctionnement.

L'hyporéflectivité bilatérale a une signification plus ubiquitaire et peut s'observer aussi bien lors

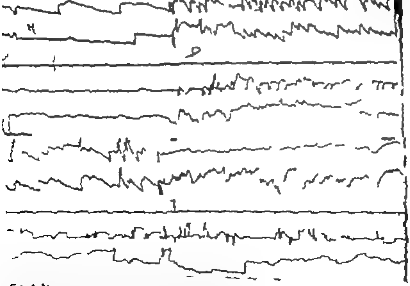

Fig. 3. Nystagmus spontané horizontal multiple dans les regards latéraux, à prédominance monoculaire, irrégulier dans un syndrome vestibulaire central (intoxication au Tegretol). Regard médian : rien; regard droit : nystagmus droit, regard gauche : nystagmus gauche.

d une atteinte vestibulaire périphérique (ablotrophie intoxication) que lors d une atteinte centrale (*affections hérédodégénératives*, insuffisance circulatoire)

L hyper réflectivité surtout bilatérale est pa contre volontiers le fait d une atteinte du systèm nerveux central Elle porte en général sur l réflectivité calorique et rotatoire et s accompagn

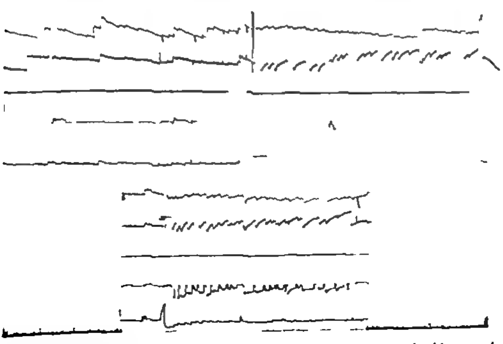

Fig 5 Dissociation inter-oculaire du nystagmus spontané dans un cas de sclerose en plaques. Regard droit discret nystagmus droit regard gauche idem au regard médian regard médian violent nystagmus gauche por tant presque uniquement sur l'œil gauche.

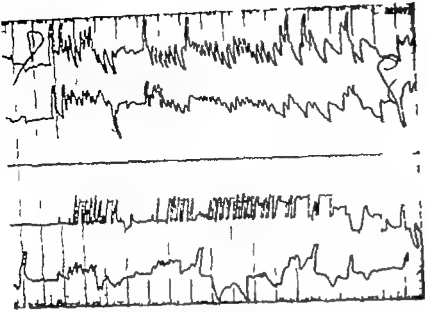

Fig. 6. Dissociation inter-oculaire du nystagmus spontané dans une ophtalmoplégie inter-nucléaire (intoxication aux hydantoïnes). Violent nystagmus horizontal droit dans le regard droit, portant essentiellement sur l'œil droit (tracé du haut) beaucoup moins sur l'œil gauche (deuxième tracé).

d'un nystagmus multidirectionnel du regard. La sclérose en plaque en est l'exemple le plus typique.

— les *altérations temporelles de la réflectivité* sont très typiques d'une atteinte centrale, fonctionnelle ou organique. L'épreuve rotatoire pendulaire qui interroge la réflectivité vestibulaire dans le temps, les fait bien apparaître.

Il en est ainsi de l'adaptation per-stimulatoire (ou tracé abrupt ou relapse vestibulaire), de l'habituation vestibulaire mise en évidence par les stimulations répétées.

— la *prépondérance directionnelle du nystagmus* est également un élément intéressant de localisation lorsqu'elle est étudiée à la fois sur la réflectivité calorique et rotatoire

Un travail statistique personnel nous a permis de tirer les conclusions suivantes: si la prépondérance directionnelle n'existe *qu'à l'épreuve* calorique et n'est pas retrouvée à l'épreuve pendulaire, l'origine centrale est pratiquement certaine: si la prépondérance à l'épreuve calorique est retrouvée à l'épreuve pendulaire, l'atteinte est presque toujours périphérique, surtout s'il existe en outre un nystagmus spontané.

— les *troubles du rythme nystagmique. Ils sont* plus ou moins marqués, allant de simples salves et inhibations intermittentes des tracés éréthiques, peu significatives, aux tracés de « petite écriture » évocateurs de l'atteinte vasculaire de l'insuffisance vertébro-basilaire, et aux tracés désarticulés ou dysmétriques (Fig. 7, 8 et 9).

Ces dysrythmies, lorsqu'elles sont nettes et permanentes, portant d'ailleurs tant sur le nystagmus spontané que sur le nystagmus provoqué par les épreuves instrumentales traduisent une *atteinte centrale*, essentiellement en rapport semble-t-il avec un altération de la réticulée pontomésencéphalique.

— Le nystagmus de position est très *fréquemment* rencontré dans les atteintes vestibulaires centrales au niveau sus-tentoriel ou au niveau de la *fosse postérieure*: affections tumorales, traumatiques, vasculaires.

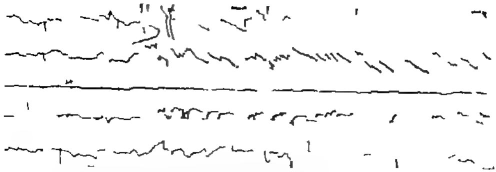

Fig 7 Troubles du rythme nystagmique. Nystagmus spontané horizontal droit dans une maladie de Friedreich.

Il n y a certes pas de nystagmus de position pathognomonique d une lésion centrale mais les caractères suivants en sont évocateurs nystagmus de type II de Nylén de direction constante apparaissant dans une ou plusieurs positions, inépuisable, reproductible ; nystagmus vertical inférieur en position de Rose discrétion ou absence habituelle des signes d accompagnement vertigineux ou végétatifs.

Ces caractères s opposent à ceux du nystagmus de position « périphérique » volontiers du type I de sens variable avec la position paroxystique s accompagnant souvent de troubles subjectifs vertigineux

— Le nystagmus d origine cervicale recherché par une épreuve simple permet d attirer l attention sur la pathologie du cou ; traumatique, vasculaire ou arthrosique

— L étude du nystagmus optocinétique bien qu il s agisse d une manifestation non vestibulaire est susceptible enfin de fournir des renseignements intéressants, d une part grâce à l étude des résultats de l interférence de la réaction optocinétique et du nystagmus spontané d autre part, grâce à la valeur topographique propre des anomalies optocinétiques.

Au cours des lésions hémisphériques l asymétrie optocinétique relève essentiellement d'une atteinte du lobe pariétal.

Au cours des lésions du tronc cérébral les perturbations du nystagmus optocinétique traduisent toujours une atteinte des voies oculogyres elles ont la valeur d une paralysie de fonction de niveau protubérantiel pour l altération du nystagmus horizontal, de niveau pédonculaire pour l altération du nystagmus vertical

Signalons enfin l intérêt de l inversion du nystagmus optocinétique dans l étude des nystagmus congénitaux

II ETUDE TOPOGRAPHIQUE ET ETIOLOGIQUE DES SYNDROMES VESTIBULAIRES CENTRAUX

A *Les atteintes du tronc cérébral*

Dans un tableau neurologique la constatation d un nystagmus et d autres signes vestibulaires oriente d abord vers une lésion du tronc céré

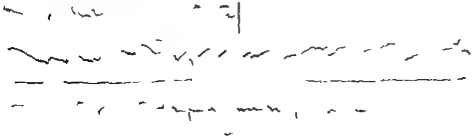

Fig 8 Troubles du rythme nystagmique. Nystagmus horizontal gauche dans une maladie de Friedreich. Regard droit nystagmus droit, regard gauche nystagmus gauche. *Désarticulation du tracé à la f*

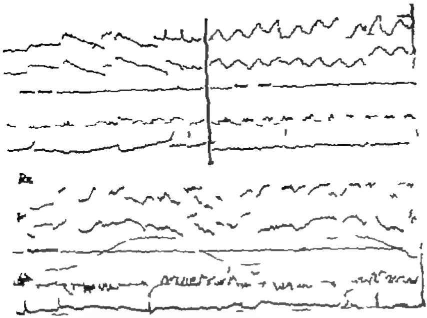

Fig. 9. La dysrythmie nystagmique se retrouve tant au niveau du nystagmus spontané, qu'au niveau de l'épreuve du mouvement de poursuite (pendule); qu'au niveau du nystagmus provoqué par l'épreuve rotatoire pendulaire. Syndrome hérédo-dégénératif.

bral c'est à dire leur fréquence et leur importance.

Toutes les affections traumatiques, dégénératives, tumorales, vasculaires, inflammatoires, lorsqu'elles touchent le tronc cérébral peuvent s'accompagner de signes vestibulaires, particulièrement d'un nystagmus.

Dans les *atteintes bulbaires*, la constatation d'un nystagmus rotatoire pur est classique et c'est dans les atteintes de cette région que l'on signale le plus fréquemment la possibilité de grands vertiges giratoires « ménièriformes », et qu'il est possible de noter des déviations nettes aux manoeuvres, cependant habituellement dysharmonieuses.

Le nystagmus rotatoire pur est très fréquent au cours de la syringobulbie, seule lésion anatomiquement précise d'atteinte bulbaire. Il est homolatéral ou croisé par rapport à la lésion suivant le stade évolutif respectivement irritatif puis déficitaire. Ce nystagmus résume presque entièrement les données vestibulaires. La réflectivité en effet est peu altérée. Il n'y a pas de vertiges.

Le syndrome vasculaire latéro-bulbaire (Wallenberg) est une éventualité beaucoup plus fréquente. Il est souvent inauguré par un grand vertige rotatoire. Le nystagmus spontané peut être *giratoire pur* mais aussi horizontal battant en général *du côté opposé à la lésion*, traduisant alors probablement une lésion plus diffuse. Les épreuves instrumentales montrent une *hyporéflectivité* uni- ou bilatérale et le plus souvent une dysrythmie nystagmique.

Dans les atteintes bulbo-protubérantielles ou protubérantielles, le syndrome vestibulaire n'est pas aussi schématique que dans les lésions bulbaires pures. anatomiquement, il peut exister des lésions de l'ensemble des noyaux *vestibulaires* primaires, mais les connexions *cérébello-vestibulaires* et vestibulo-oculogyres expliquent que dans la plupart des cas, *il existe une association* de facteurs.

Sur le plan étiologique, cette région est essentiellement *atteinte soit* par des lésions vasculaires d'origine basilaire, soit par des tumeurs (du tronc, *du 4ᵉ* ventricule ou des annexes venant comprimer *le tronc*), soit dans la sclérose en plaques. *Dans l'un ou l'autre de ces cas, les lésions* sont habituellement assez diffuses et difficiles à systé-

matiser Le nystagmus horizontal ou multidirectionnel est le plus souvent rencontré.

Dans les cas de tumeurs, la *composante verticale* est fréquente pour les localisations médianes la composante horizontale pour les localisations latérales.

La réflectivité aux épreuves est modifiée de façon variable mais deux *altérations* sont souvent rencontrées la prépondérance directionnelle du nystagmus qui répond à la description de la dysréflexie oculovestibulaire croisée de Barre, pouvant aboutir à l'hémi avestibulie, et les troubles du rythme nystagmique avec désorganisation du pattern au niveau du tracé comme au niveau « élémentaire » de la secousse, traduisant l atteinte de la réticulée mésencéphalique et de la bandelette longitudinale postérieure Il s agit là d ailleurs de lésions du versant oculogyre du réflexe vestibulo-oculogyre, dont la spécificité vestibulaire peut être discutée

Dans les atteintes pédonculaires Le nystagmus spontané vertical pur est classique (tumeurs de la calotte, syndrome alterne de Weber encé phalopathie de Gayet Wernicke) Il est volontiers dissocié, plus rarement un nystagmus rétractorius, extravestibulaire peut se manifester

Ce type de nystagmus vertical apparaît essentiellement comme une perturbation de la motricité oculaire conjuguée verticale et son origine vestibulaire est plus que discutable (véritable « pace maker » anormal sur les voies de la verticalité)

Le nystagmus vertical s associe d ailleurs très souvent aux paralysies de la verticalité et aux altérations du nystagmus optocinétique vertical. Il n existe habituellement pas de perturbations aux épreuves vestibulaires, mais leur interprétation peut être délicate du fait de signes oculomoteurs spontanés et aussi de la fréquente interruption « fonctionnelle » des liaisons vestibulo-oculomotrices, et on peut faussement conclure dans ces cas à *une aréflexie* vestibulaire du fait de l'absence de réponse nystagmique aux stimulations caloriques ou rotatoires.

B *Dans les affections du cervelet* essentiellement d origine tumorale dégénérative quelquefois infectieuse (abcès du cervelet) il existe très fréquemment un nystagmus horizontal multiple ou vertical.

— il peut être *spécifiquement cérébelleux* nystagmus des regards latéraux, souvent pendulaire, tremblement du regard « nystagmus postural » d Alajouanine et Lhermitte
— il s agit le plus souvent d un nystagmus « vestibulaire des cérébelleux » le trouble de la *fonction cérébelleuse* modifiant les caractères du nystagmus vestibulaire nystagmus spontané multiple irrégulier dysmétrique visqueux, crocheté tous ces caractères sont retrouvés également pour le nystagmus provoqué par les épreuves caloriques et rotatoires.
— le nystagmus de position est très fréquent dans les atteintes cérébelleuses.

C. *Dans les atteintes de la base* (Parkinson, encéphalites), le nystagmus spontané est rare mais on rencontre par contre souvent des perturbations de l oculomotricité désordre des mouvements oculaires volontaires, successions de saccades, altérations du mouvement de poursuite

D *Au cours des atteintes hemispheriques* les troubles vestibulaires sont contingents nystagmus spontané rare épreuves instrumentales *habituellement normales, mis à part* la possibilité d une prépondérance directionnelle du nystagmus, retrouvée d ailleurs également à *l'épreuve optocinétique ce qui fait mettre en* doute son caractère vestibulaire spécifique Le nystagmus de position est quelquefois rencontré.

Contrastant avec la discrétion des troubles vestibulaires, les troubles de l équilibration dont l origine est d ailleurs fort complexe sont fréquents.

Ces constatations semblent bien confirmer les données physiopathologiques concluant actuellement à l absence de projections vestibulaires corticales spécifiques.

CONCLUSION

Il faut souligner les difficultés de la définition et des limites des syndromes vestibulaires cen

traux. Il convient surtout de replacer le rôle de l'appareil vestibulaire dans le grand mécanisme de l'*équilibration*.

Sur le plan physiopathologique, il semble préférable de proposer une division de l'appareil vestibulaire en deux niveaux, qu'il n'appartient plus de qualifier formellement de « périphérique » ou de « central ».

Un niveau de réception et de transmission qui comprend, outre le récepteur labyrinthique et le nerf vestibulaire, les noyaux vestibulaires primaires ou tout au moins la jonction interneuronale. Son atteinte est responsable de vertiges systématisés (dans les *lésions* aigues), de nystagmus intense, habituellement régulier et unisens, de déviations, d'altérations harmonieuses aux épreuves. Au cours des maladies du système nerveux central, il est rencontré surtout dans les syndromes vasculaires (insuffisance vertébro-basilaire permanente, Wallenberg), et certaines formes de sclérose en plaques.

Un niveau d'intégration qui comprend les liaisons des noyaux vestibulaires primaires au système oculo-moteur au cervelet, à la moelle principalement, mais aussi à l'ensemble de l'appareil d'équilibration y compris ses afférences conscientes.

Les lésions du système nerveux central qui touchent cet étage ne seront donc jamais univoques, et s'il y a atteinte prédominante des structures vestibulaires centrales, les signes seront habituellement parcellaires, variables et surtout *associés ou combinés*.

Toutes les atteintes du système nerveux, mais particulièrement celles du tronc cérébral pourront en être responsables, qu'elles soient vasculaires, traumatiques, inflammatoires, tumorales, dégénératives.

La spécificité vestibulaire de leurs manifestations cliniques ou instrumentales peut cependant souvent prêter à discussion et il reste toujours nécessaire de les intégrer à l'ensemble de l'étude du système nerveux.

DIE REAKTION DER MITTELOHRSCHLEIMHAUT BEI TUBENVERSCHLUSS[1]

W. Arnold und K. H. Vosteen

Aus der Hals-Nasen-Ohrenklinik der Universität Frankfurt/M., Bundesrepublik Deutschland

Abstrakt 1. Ein Verschluß der Ohrtrompete bewirkt durch den sehr rasch einsetzenden Unterdruck in der Pauke nach wenigen Stunden eine erheblich vermehrte Passage von Extrazellularflüssigkeit durch das Schleimhautepithel hindurch in das Lumen der Paukenhöhle. Nach 24 Stunden kommt es zur Ruptur der Interzellularbrücken und die Flüssigkeit des subepithelialen Raumes ergießt sich frei in die Pauke.

2. Bei anhaltendem Unterdruck in den Mittelohrräumen beobachtet man eine zelluläre Umdifferenzierung der vormals flachen Epithelzellen zu hochprismatischen Epithelzellen mit neuartiger Funktion. Das einschichtig flache Epithel wird beinahe vollständig durch zylindrische kinozilientragende oder sekretorisch aktive Zellen ersetzt.

3. Frühzeitige Belüftung des „Hydrops ex vacuo" führt zu einem Sistieren der epithelialen Umwandlung, jedoch nicht zu einer Rückbildung auf den ursprünglichen epithelialen Zustand.

4. Untersuchungen an menschlichen Schleimhautproben des Mittelohres zeigen, daß die Schleimhautveränderungen bei seröser Otitis den gleichen Gesetzen unterworfen sind, wie sie sich im Tierexperiment reproduzieren lassen.

Ohrtrompete und *Mittelohrräume* bilden sowohl anatomisch als auch funktionell eine Einheit (Link & Handl, 1954; Handl & Link, 1954; Feldmann, 1973*a*, *b*). So führen stenosierende Veränderungen im Bereich des Tubenverlaufes zwangsläufig zu pathophysiologischen Auswirkungen auf die lufthaltigen Räume des Mittelohres, deren morphologisches Substrat sich in einer Veränderung des epithelialen Gefüges der Mittelohrschleimhaut niederschlägt. Wie wir anhand von Trazerstudien im Tierexperiment zeigen konnten (Arnold, 1971) besteht zwischen Liquor cerebrospinalis, der Perilymphflüssigkeit des *Innenohres* und der Extrazellularflüssigkeit des subepithelialen *Raumes der Mittelohrschleimhaut eine offene Kommunikation*. Zude[m] wurde der Nachweis erbracht, daß Flüssigke[it] aus dem Interstitium des subepithelialen Raum[es] auf cytopemptischem Wege ständig an d[ie] Oberfläche des Schleimhautepithels transportie[rt] wird. Die umgekehrte Richtung, *nämlich* e[in] cytopemptischer Transport von der Oberfläch[e] des Mittelohrschleimhautepithels in den sub[-] mukösen Raum hinein scheint nach Untersu[-] chungen von Höft (1969) nicht möglich zu sein. Somit konnte nachgewiesen werden, daß d[ie] normale Mittelohrschleimhaut nur in eine[r] Richtung, nämlich vom subepithelialen Raum zur Paukenhöhle Flüssigkeit transportiert. Al[s] Ergebnis einer anschließenden Untersuchung (Arnold, 1972) konnten wir feststellen, daß e[s] nach Provokation eines Paukenergusses durch Verkauterung des Tubenostimus zuerst zu einem *vermehrten transepithelialen cytopemptischen* Transport von Extrazellularflüssigkeit an die Oberfläche der Mittelohrschleimhaut kommt und wenige Stunden später der zunehmende hydrostatische Druck im subepithelialen Raume eine Ruptur der epithelialen Schlußleisten bewirkt. Zu diesem Zeitpunkt kann subepitheliale Extrazellularflüssigkeit ohne zelluläre Barriere frei in das Lumen der Paukenhöhle übertreten, wobei man elektronenmikroskopisch nachweisen kann, daß nun auch in zunehmendem Maße ein *Gefäßtranssudat bei der Produktion* der Flüssigkeit beteiligt ist. Gleichzeitig beobachteten wir eine sehr rasch eintretende Umwandlung des epithelialen Bildes. Ortsständige *flache* Epithelzellen wurden durch hochprismatische schleimproduzierende Zellen ersetzt. Diese be-

[1] Herrn Prof. Dr. Tadashi Fukuda, University School of Medicine, Gifu, Japan in Verehrung gewidmet.

rem vielfach beschriebene epitheliale Metaplasie (Holmgren, 1940; Sadé et al., 1959; Senturia et al., 1961; Senturia et al., 1962, Senturia, 1963, ...71; Friedmann, 1963; Sadé, 1966; Reiner & ...ner, 1968; Paparella et al., 1970; Proud et al., ...70; Arnold, 1972) muß zu einer neuartigen ...aktion der Epithelzellen führen.

Zweck der vorliegenden tierexperimentellen ...nd vergleichenden Untersuchung soll es sein ...ufzuzeigen, bis zu welchem Zeitpunkt Veränderungen an der Mittelohrschleimhaut bei stenosierender Ohrtrompete durch bald einsetzende Belüftungsmaßnahmen reversibel sind und von welchem morphologischen Zustandsbild ab die metaplastisch umgewandelte Mittelohrschleimhaut eine nicht mehr zu beeinflussende selbständige Funktion übernommen hat.

Voraussetzung für derartige *Untersuchungen* ist eine genaue Kenntnis der normalen epithelialen Verhältnisse beim angewandten Laboratoriumtier und beim Menschen. Lim et al. (1967) untersuchten elektronenmikroskopisch die Auskleidung der Eustachi'schen Röhre und die Region des tympanalen Tubenostiums beim Meerschweinchen. Hier fanden sie schleimproduzierendes Epithel durchsetzt von Becherzellen und Zellen mit dunklen Schleimblasen, die insbesondere in der Übergangszone zwischen tympanalem Tubenostium und Hypotympanon zu finden waren. Hussl & Lim (1969), Hentzer (1970) und Lim et al. (1973) beschrieben die Ultrastruktur der Mittelohrschleimhaut des Menschen anhand von Autopsiematerial, wobei sie sich *fast ausschließlich dem tubenauskleidenden Epithel und der Übergangszone* zwischen tympanalem Tubenostium und Hypotympanon zuwandten. Sie konnten zeigen, daß insbesondere in der Übergangszone von Tube zu Hypotympanon zilientragende Zellen vorkommen, gelegentlich auch vereinzelte Schleimzellen. Andere Veröffentlichungen, denen zufolge der Schleimhaut des Mittelohres grundsätzlich *in allen* topographischen Bereichen sekretorische Funktion zugesprochen wird, können nur mit vorsichtiger Kritik aufgenommen werden (Bak Pedersen & Tos, 1971*a*, *b*), nicht nur weil das Material von Toten entnommen wurde, deren Anamnese nicht bekannt war, sondern weil mehrfach belegt wurde, daß jede *länger anhaltende* Tubenfunktionsstörung zu einer epithelialen Umwandlung der Mittelohrschleimhaut führt (Friedmann, 1955; Senturia et al., 1962, Zechner et al., 1968; Lim & Birck, 1971; v. Ilberg & Arnold, 1972, *Arnold & v. Ilberg, 1973*; Arnold, 1972). Wenn Sadé (1966) die menschliche Mittelohrschleimhaut gleichsetzt mit „respiratorischem Epithel", so trifft das sicherlich für die unbelastete gesunde menschliche Mittelohrschleimhaut nicht zu. Auch eine *entzündungsfreie* Mittelohrschleimhaut nach Tympanoplastik ist keinesfalls wie Schöndorf (1974) vermutet, identisch mit gesunder, nicht vorbelasteter Schleimhaut. Das mehrschichtigem zilientragende und sekretorisch potente Epithel ist ebenso wie die starke Fibrosierung der Submucosa ein Hinweis für den vorangegangenen entzündlichen Prozeß. Hier liegt eine echte metaplastische Umwandlung vor, auf die wir experimentell (Arnold, 1972) und vergleichend (Arnold & v. Ilberg, 1973) aufmerksam gemacht haben. Selbst Gewebeproben von der ovalen Fensternische, von der Fußplatte oder vom Promontorium — im Verlaufe einer Otosklerose-Operation gewonnen — dürfen keinesfalls für „normale" Mittelohrschleimhaut angesehen werden, wie es Schöndorf & Mäusle (1973) taten. Ihre vorgelegten Abbildungen weisen eindeutig jene Veränderungen auf, wie wir sie in einer ausgedehnten Untersuchungsreihe als kennzeichnend für Schleimhautveränderungen bei Otosklerose sahen (Arnold & Plester 1974). *Dagegen ließen zahlreiche* Biopsien von Mittelohrschleimhaut, welche bei Otosklerosekranken fern vom Otoskleroseherd entnommen wurden, in allen Fällen ein flaches bis kubisches Epithel erkennen, in das gelegentlich eine einzelne zilientragende Zelle eingestreut lag, das jedoch ohne Ausnahme keine schleimproduzierenden Zellen trug (vergl. Kawabata & Paparella, 1969; Paparella, 1973).

Grundsätzlich können wir davon ausgehen, daß die unbelastete, gesunde Mittelohrschleimhaut beim Meerschweinchen (Lim et al., 1967; Haye, 1973; Hussl & Lim, 1969), wie auch die des Affen (Kawabata & Paparella, 1971) und

4 753434

die des Menschen (Gosepath, 1964 Eckert Möbius 1926 Bargmann 1962 Hussl & Lim, 1969) mit Ausnahme des Tubenwinkels ein flaches, zilienloses und schleimdrüsenloses Epithel aufweist Veränderungen des epithelialen Gefüges im Tierexperiment und bei bestimmten Schleimhauterkrankungen des menschlichen Mittelohres werden wir nach diesen Ausgangskriterien interpretieren

MATERIAL UND METHODE

I) Bei 24 Meerschweinchen wurde in Nembutalnarkose das epipharyngeale Tubenostium der rechten Seite mit einem Thermokauter verödet (Methodik, Arnold 1972) und anschließend die Tiere nach 10 16 20 24 und 48 Stunden sowie nach 3 6 8 und 14 Tagen durch korporale Perfusion mit 6,2 %igem Glutaraldehyd (Karlsson & Schultz, 1965) getötet 30 Minuten vor der korporalen Perfusion wurde die Membrana atlanto-occipitalis freigelegt und 100 μl Thorotrast in die Cisterna cerebello-medullaris injiziert. Nach anschließender Immersionsfixation des entsprechenden rechten Felsenbeines wurden Schleimhautproben vom ovalen Fenster vom Schleimhautüberzug der Cochlea und vom runden Fenster entnommen in Phosphatpuffer ausgewaschen und mit Osmiumtetroxyd (1 %ig) nachfixiert, in Alkohol dehydriert und schließlich in Epon (Luft, 1961) eingebettet Zur Kontrolle wurden von der linken Bulla tympanica ebenfalls die topographisch korrespondierenden Schleimhautstellen entnommen und zur Untersuchung miteingebettet

II) Kreuzversuch Um sicherzustellen, daß tatsächlich nur die durch den Tubenverschluß hervorgerufenen hydrostatischen Veränderungen für die Schleimhautmetaplasie verantwortlich sind wurde in einer weiteren Untersuchungsreihe bei 9 Meerschweinchen unter gleichen experimentellen Bedingungen wie oben vorgegangen, allerdings wurde bei diesen Tieren nach 20 Stunden 24 Stunden 2 Tagen, 4 Tagen und 15 Tagen jeweils das rechte Trommelfell total entfernt, um den Einfluß einer Belüftung auf die weitere Reaktion der Mittelohrschleimhaut bei verschlossener Ohrtrompete zu studieren Alle Tiere wurden bis zur Tötung antibiotisch mit Ambliosin (Hoechst) abgedeckt. Demzufolge konnten wir bei keinem Tier Zeichen einer bakteriellen Entzündung licht wie auch elektronenmikroskopisch erkennen.

III) Bei 7 Patienten wurde während einer Stapesmobilisation wegen Otosklerose Schleimhaut fern vom otosklerotischen Herd entfernt (vorderer Anteil der runden Fensternische, Fazialiskanal, Promontorium) und zur vergleichenden Untersuchung elektronenmikroskopisch aufgearbeitet

IV) Zum weiteren Vergleich wurden Schleimhautproben von 12 Patienten mit fadenziehendem oder wässrigem Paukenguß entnommen, bei denen entweder eine erweiterte Parazentese oder eine Paukenrevision vorgenommen worden war Die Schleimhautproben wurden vom Promontorium, von der Gegend des runden Fenster oder vom Aditus ad antrum gelöst. Die Immersionsfixation und Weiterbehandlung dieser Gewebeproben erfolgte mit gleicher Methodik wie oben. Die elektronenmikroskopischen Dünnschnitte wurden mit Bleicitrat (Reynolds, 1963) und Uranylazetat (Huxley & Zubay 1961) nachkontrastiert. Von allen eingebetteten Geweben wurden Schnitte zur histographischen Orientierung angefertigt und mit Paraphenyldiamin oder Azur 2 Mallory gefärbt.

BEFUNDE

I) Die normale nicht vorbelastete Mittelohrschleimhaut des Meerschweinchens ist aus zwei Schichten aufgebaut Sie besteht aus einer einschichtigen, flachen Epithellage die an der Oberfläche nur vereinzelt kurze Mikrovilli trägt. Das Cytoplasma ist aufgelockert und beinhaltet in der Regel zahlreiche optisch leere pinozytotische Bläschen Gegen das tympanale Tubenostium hin geht das flache Epithel in ein kubisches Epithel über das an vielen Stellen nun zweireihig ist, bestehend aus einer basalen Zellage von kleinen runden Zellen und einer hochprismatischen zilientragenden Epithelschicht. Dazwischen sind schleimproduzierende

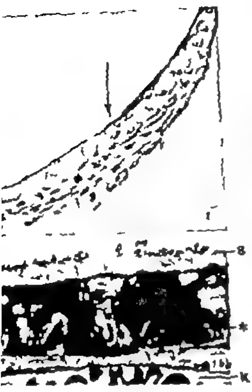

Abb. 1. (a) Lichtmikroskopische Wiedergabe der histologischen Verhältnisse im Tubenwinkel (Meerschweinchen). ↗ plötzlicher Übergang von flachem zu hochprismatischem Epithel. × 450 (b) Undifferenziertes Epithel vom Schleimhautüberzug der Cochlea 3 Tage nach Verödung des gleichseitigen Tubenostiums. Über dem mehrschichtigen sekretorischen Epithel liegt ein dünner Schleimfilm (S); K, weitgestellte Kapillare; nach basal abgedrängte Epithelzelle (vgl. Abb. 3). × 1250

Zellen eingestreut. Die Grenze von flachem Epithel zu hochprismatischem zweischichtigem Epithel ist beim *Meerschweinchen plötzlich* (Abb. 1). Die nach basal folgende submuköse Schleimhautschicht umfaßt den Bereich zwischen Epithel mit Basalmembran und knöcherner Unterlage. Dieser Raum wird von einem sehr lockeren, weitmaschigen fibrozytären Gewebe gestaltet, in dessen Maschen lockere Bündel von kollagenen und wenigen elastischen Fasern verlaufen. Die vereinzelt anzutreffenden, teilweise mit glatter Muskulatur ausgestatteten Gefäße liegen unterhalb der Basalmembran und können die Epithelschichten in das Lumen der Paukenhöhle vorwölben.

Gelegentlich trifft man Bündel von Nervenfasern in der submukösen Schicht, die von einer flachen Schwannschen Zellage umgeben sind und nur in seltenen Fällen eine Myelinisation zeigen. Diese Nervenbündel sind der Jacobsonschen Anastomose zuzuordnen. Gegen den angrenzenden Extrazellularraum sind die Axonenbündel mit einer dichten Basalmembran abgegrenzt. Eine besondere *Stellung* nimmt die Membran des runden Fensters ein, bei der es infolge fehlender knöcherner Wandstruktur der Cochlea zu einem freien Übertritt von perilymphatischer Flüssigkeit in die weiten Extrazellularräume der Submucosa kommt. Eine zelluläre Barriere zwischen Scala tympani und subepithelialem *Raum* besteht nicht. *Hier* verbindet sich das mesenchymale, locker geschichtete Endost der Cochlea mit dem Fibrozytenschwamm der Submucosa und gestattet den Flüssigkeiten freien Austausch.

II) Die Ergebnisse dieser Versuchsserie, bei der in bestimmten Zeitabständen nach Verödung der Tube Mittelohrschleimhaut untersucht wurde, stimmen mit früheren Befunden (Arnold, 1972) überein. 10 Stunden nach *Verödung der Tube beim Meerschweinchen* bemerkt man eine erhebliche Vermehrung der Pinocytosebläschen im Epithel als Ausdruck einer zunehmenden cytopemptischen Tätigkeit. Gleichzeitig kommt es zu einer Erweiterung des interzellulären Raumes zwischen den Epithelzellen. Nach 16 Stunden sieht *man*, daß die weit gestellten Interzellularräume mit Bündeln von kollagenen *Fasern ausgefüllt* sind. Schließlich kommt es zur *Ruptur der Interzellularbrücken* und die Flüssigkeit des subepithelialen Raumes strömt in die *Paukenhöhle*. Schon vorher kann man an vielen Epithelzellen die ersten Anzeichen einer zellulären *Gegenreaktion feststellen*. *Das* ursprünglich gleichförmig helle Grundcytoplasma nimmt an elektronendichter Substanz zu, wobei es zu einer *Vermehrung* von lysosomalen Strukturen und Mitochondrien kommt. Zellkerne zeigen tiefe Einschnürungen sowie eine Umorientierung ihrer *Chromatinstruktur*. Der gesamte Zelleib quillt auf. So entsteht aus der vormals langgezogenen, flachen Epithelzelle eine kubische bis

hochprismatische Zelle, die zur benachbarten Epithelzelle hin pseudopodienartige Ausläufer entsendet. Zwischen diesen Ausläufern entwickeln sich primitive Schlußleisten im Sinne von Zonulae adhaerentes. Verschiedene Anzeichen, wie die erwähnte Chromatin-Umorientierung, die tiefen Kerneinbuchtungen, das Auftreten von Zentriolen im Grundcytoplasma und die vielerorts plötzlich vorhandene Mehrschichtigkeit des Epithels lassen Zellteilungsvorgänge vermuten (Abb. 2*a*, *b*).

Im apikalen Cytoplasmabereich der neuartigen hochprismatischen Epithelzellen liegen etwa einen Tag nach Verschluß der Ohrtrompete relativ elektronendichte, opake, kreisrunde Einschlüsse. Basal entsenden diese Zellen sehr lange, sich verzweigende Ausläufer, welche in die weit offenen, benachbarten Interzellularfugen hineinreichen und mit den ortsständigen Epithelzellen Interzellularbrücken ausbilden. An der basalen Fläche erkennt man die Neubildung von Basalmembranen.

Nach 48 Stunden lassen sich stark erweiterte und rupturierte Interzellularspalten mit Austritt von subepithelialer Flüssigkeit nurmehr im Bereich des runden Fensters nachweisen, wogegen sich in fast allen anderen Bereichen des Mittelohres ein neuartiges epitheliales Gefüge ausgebildet hat. In den basal noch weit offen stehenden Interzellularräumen liegen abgerundete, ursprüngliche Epithelzellen, die zum Teil noch mit großen, wassergefüllten Blasen in ihrem Cytoplasma ausgefüllt sind. Darunter hat sich eine kontinuierliche, an keiner Stelle unterbrochene *Basalmembran* formiert. An ihrer lumenwärts gerichteten Oberfläche zeigen die hoch-

er das runde Fenster in die weiten Extrazellu-
rräume der Mittelohrschleimhaut gelangt, nun
urch die starke Bindegewebsvermehrung zu-
ückgehalten wird und nunmehr in den weni-
en, vorzugsweise basal gelegenen Lymphspalten
achzuweisen ist (Abb. 4). Der rege cytopemp-
ische Flüssigkeitstransport aus dem subepithe-
len Raum durch das Epithel hindurch an die
Oberfläche der Schleimhaut läßt sich jetzt nicht mehr nachweisen. Der Sekretionstyp der sekretorisch aktiven Epithelzellen läßt eine apokrine und ekkrine Sekretion unterscheiden (Abb. 5, 6).

III) Um zu entscheiden, ob diese Umdifferenzierungsvorgänge des Epithels, welche zweifellos auf das Vakuum in den Mittelohrräumen nach Tubenverschluß zurückzuführen sind, gestoppt werden können oder sogar reversibel sind, wurde

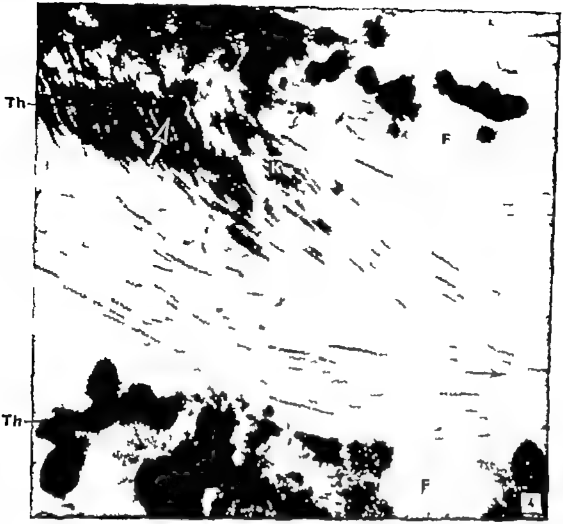

Abb 4 [illegible] Tage nach Tubenverschluß beginnt das subepitheliale Mesenchym sich zu verdichten, durch eine enorme Produktion kollagener Fasern (*K*). *F* Fibrocyten *Th* phagocytiertes Thorotrast, das 30 Minuten vor der Tötung in den Liquor injiziert wurde nur noch wenig freies Thorotrast ist im Interzellularraum nachweisbar (↗) × 4000.

prismatischen Zellen neben langen Mikrovilli Bündel von Kinozilien, die mit typischen Basalkörperchen im apikalen Cytoplasma verankert sind (Abb 3) Daneben unterscheidet man schleimproduzierende Zellen, von denen die eine Sorte elektronendichte membranbegrenzte und opake Schleimblasen in das Lumen der Paukenhöhle entleeren andere wiederum sehr helle mit staubförmigem Material beladene und nicht membranbegrenzte Blasen in das Lumen der Paukenhöhle ausstoßen Der vormals weitmaschige flüssigkeitsgefüllte subepitheliale Raum hat eine sehr starke Zunahme an kollagenen Fasern erfahren, die nun den Platz der weiten Interzellulärräume beinahe vollständig ausfüllen Insgesamt ist der subepitheliale Raum um eine Vielfaches seiner ursprünglichen Breite erweitert

Nach 8–14 Tagen erkennt man in allen Schleimhautbereichen des Mittelohres ein gleichförmiges Epithelmuster bestehend aus hochprismatischen, kinozilientragenden Zellen dazwischen seröse und mukose Schleimzellen Der stark verbreiterte submuköse Raum ist von Fibrozyten und dichten kollagenen Bündeln vollständig ausgefüllt Hierdurch wird die Flüssigkeitsverschiebung innerhalb der Interzellularspalten zum Epithel hin entscheidend behindert Man kann nachweisen, daß eine in den Liquor injizierte Indikatorlösung, welche normalerweise über die bekannten Liquorabflußbahnen zu den Perilymphräumen des Innenohres und von dort

Abb. 5. 14 Tage nach Tubenverschluß. Komplett umdifferenziertes Epithel aus dem Bereich des Runden Fensters. L, Lumen der Paukenhöhle; Z, Zilientragende Epithelzellen apokrine Sekretion. 4000.

über das runde Fenster in die weiten Extrazellularräume der Mittelohrschleimhaut gelangt, nun durch die starke Bindegewebsvermehrung zurückgehalten wird und nunmehr in den wenigen, ortsweise basal gelegenen Lymphspalten nachzuweisen ist (Abb. 4). Der rege cytopemptische Flüssigkeitstransport aus dem submukösen Raum durch das Epithel hindurch an die Oberfläche der Schleimhaut läßt sich jetzt nicht mehr nachweisen. Der Sekretionstyp der sekretorisch aktiven Epithelzellen läßt eine apokrine und ekkrine Sekretion unterscheiden (Abb. 5, 6).

In einer weiteren Versuchsserie bei 9 Meerschweinchen zur Wiederbelüftung der Paukenhöhle 20 Stunde 24 Stunden 2 Tage 4 Tage und 14 Tage nach Verödung des rechten epipharyngealen Tubenostiums das gleichseitige Trommelfell entfernt Es zeigte sich daß eine Entfernung des Trommelfells nur während der ersten 48 Stunden einen Einfluß auf die morphologischen Veränderungen der Mittelohrschleimhaut hatte Die weit geöffneten Interzellularspalten aus denen Flüssigkeit aus dem subepithelialen Raum in das Mittelohrlumen gelangte konnten sich wieder schließen. Jene Zellen die sich zu hochprismatischen Epithelzellen mit Anzeichen einer Schleimsekretion umgewandelt hatten blieben an Ort und Stelle liegen zeigten jedoch keine weiteren Veränderungen insbesondere keine nachweisbare aktive Schleimproduktion War es dagegen bereits mit einer vollständigen Umwandlung des Epithels mit einem aktiv sekretorischen Epithel gekommen so bewirkte eine auch lang dauernde Belüftung des Mittelohres keine Rückbildung des neuen Epithelmusters mehr Wurde beispielsweise 2 Tage nach Verödung des Tubenostiums das Trommelfell entfernt und die Mittelohrschleimhaut 8–14 Tage

Abb. 7. Menschliche Mittelohrschleimhaut über dem Facialiskanal (fern vom Otoskleroseherd entnommen). *L*, Lumen der Paukenhöhle; *E*, Epithelzelle, flach; *F*, subepithelialer Fibrocyt; *K*, Kollagen. 18 000.

später untersucht, so fanden wir in der Regel ausgedehnte inselförmige Areale eines hochprismatischen, kinozilientragenden und schleimproduzierenden Epithels, und im Lumen der Paukenhöhle lag über dem Epithel ein zarter Schleimfilm (Abb. 16).

IV) Die normale Mittelohrschleimhaut des Menschen unterscheidet sich in den Mittelohrregionen (Promontorium, runde Fensternische, Facialiskanal), die wir in dieser Untersuchungsreihe kontrolliert haben, nicht von der des Meerschweinchens. An keiner Stelle fanden wir schleimproduzierende Zellelemente und nur in ganz seltenen Fällen kleine Inseln von kinozilien-tragenden kubischen Zellelementen. Untersuchungen der Schleimhautverhältnisse des runden Fensters konnten wir aus verständlichen Gründen nicht durchführen (Abb. 7).

Gewebeproben von Patienten mit seröser Otitis bei undurchgängiger Ohrtrompete zeigten bei elektronenmikroskopischer Aufarbeitung die gleichen morphologischen Verhältnisse wie im Tierexperiment etwa nach 24 Stunden. Erweiterte Interzellularspalten, Eröffnung der Interzellularspalten zum Lumen der Paukenhöhle hin, Ausschleusen von untergehenden Zellresten zusammen mit Flüssigkeit in das Lumen der Paukenhöhle, sowie eine starke Aufladung des Cytoplasmas der Epithelzellen mit flüssigkeitsgefüllten Bläschen (Abb. 8). Bei chronisch fadenziehendem Paukenerguß wechselten Regionen von flachem, verklumptem Epithel mit hochprismatischem, zilientragendem schleimproduzierendem Epithel ab (Abb. 9*a*). In den menschlichen Schleimhautproben war vorwiegend eine apokrine Sekretion des umgewandelten Epithels zu

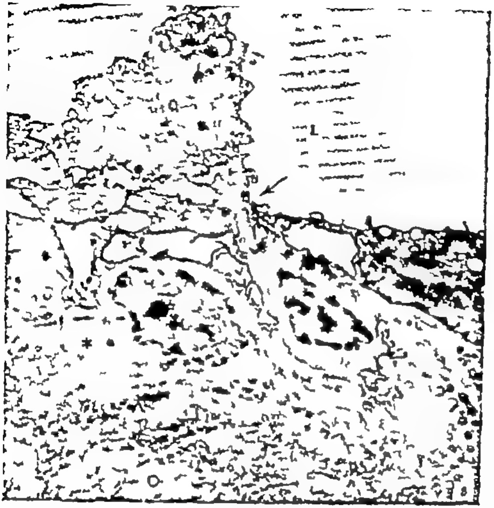

Abb 8 Menschliche Mittelohrschleimhaut unter dem Facialiskanal bei serösem Paukenerguß weite, offene Interzellularspalten ○ eiweißreiches Transsudat im Interstitium *Bm*, Basalmembran eröffneter Interzel larspalt *L*, Lumen der Paukenhöhle. 18 000.

erkennen (Abb 9*b*) Die subepitheliale Zellage hatte stark an Volumen und Substanz zugenommen hervorgerufen durch eine extrem starke Zunahme mesenchymaler Zellelemente An reaktiven Zellen fanden wir häufig Histiozyten (*eosinophile Leukozyten, Mastzellen und Makrophagen*) bakteriologische Untersuchungen sowohl des wässrigen als auch des fadenziehenden schleimigen Paukenergusses verliefen stets negativ

Zusammenfassung der Befunde

1 Beim Verschluß der Ohrtrompete kommt es schon nach wenigen Stunden zu einer vermehrten Passage von Extrazellularflüssigkeit durch das Schleimhautepithel hindurch in das Lumen der Paukenhöhle Nach 24 Stunden tritt eine Ruptur der Interzellularbrücken ein und d Flüssigkeit des subepithelialen Raumes ergie sich frei ins Lumen der Paukenhöhle

2 Bei anhaltendem Unterdruck in den Mitte ohrräumen beobachtet man eine Regeneratio mit *Umdifferenzierung der ursprünglichen Ep* thelzellen so daß als Folge zylindrische Epithe zellen auftreten, die sich entweder als kinozilier tragende Zellen oder als sekretorisch aktiv Schleimzellen differenziert haben

3 Frühzeitige Belüftung des unter Unterdruc stehenden Mittelohres kann zu einem Sistieren *der epithelialen Umdifferenzierung führen* je doch nicht zu einer Rückbildung auf den ur sprünglichen epithelialen Zustand

4 Untersuchungen an menschlichen Schleimhautproben des Mittelohres zeigen, daß die Schleimhautveränderungen bei seröser Otitis den

gleichen Gesetzen unterworfen sind wie sie sich im Tierexperiment reproduzieren lassen (Tabelle I).

DISKUSSION

Bei ausbleibendem Druckausgleich in den Mittelohrräumen, dessen Ursache entweder in Veränderungen im Bereich des Epipharynx oder im Tubenverlauf zu suchen sind, entsteht in zunehmendem Maße ein Unterdruck in den Mittelohrräumen. Die dabei auftretenden physikalischen Kräfte wirken durch Zug an den Wänden dieses Raumes. Dieser Zuge bewirkt einen zunehmenden hydrostatischen Druck im Bereich der Extrazellularflüssigkeit der Submucosa, der bald so stark sein wird, daß er die epithelialen Interzellularfugen sprengt, wodurch subepitheliale Flüssigkeit in das Lumen der Paukenhöhle austritt. Zuvor schon kommt es zu einer ultrastrukturell sehr deutlich erkennbaren Zunahme einer cytopemptischen Tätigkeit der Epithelzellen. In vermehrtem Maße wird Flüssigkeit des subepithelialen Raumes zur Oberfläche der Epithelzellen geschleust und dort ausgestoßen (Arnold, 1972). Die Ursache des zunehmenden Unterdruckes in den Mittelohrräumen bei verschlossener Tube und intaktem Trommelfell liegt nun darin, daß sich das Gasgemisch in der Mittelohrräumen, bestehend aus Sauerstoff, Stickstoff und Kohlendioxyd mit den gleichen Gasen im Gewebe auseinandersetzt und einen Ausgleich des Partialdruckes „Gasgemisch-Mittelohrräume" und „Gasgemisch-Gewebe" zu erreichen sucht. Da der Partialdruck der im Mittelohr befindlichen Gase mit Ausnahme des CO_2 höher ist als der im Gewebe, diffundiert ständig Stickstoff und Sauerstoff in das Gewebe hinein. Dadurch entsteht durch Abnahme der Gesamtgasmenge in den Mittelohrräumen bei gleichbleibendem Mittelohrvolumen ein Unterdruck (Feldmann, 1973), der nach Erschöpfen der Elastizitätskraft des Trommelfelles und der anderen beweglichen Membranen des Mittelohres (runde Fenstermembran, ovales Fenster) auf ein starres System einwirkt. Dadurch wird Flüssigkeit aus dem wasserreichen Mucoperiost an die Oberfläche gesaugt, wobei sich nach einer ursprünglichen Weitstellung der Kapillaren der Submucosa auch ein Gefäßtranssudat beimischt, an dem Austritt von Erythrozyten in die Submucosa wird erkenntlich, daß es in zunehmendem Maße auch zu einem Exsudat kommt (Arnold, 1972). Der fortbestehende hydrostatische Druck der Submucosa bewirkt schließlich die Ruptur der epithelialen Kittleisten, wodurch die Flüssigkeit des subepithelialen Raumes, bestehend aus Extrazellularflüssigkeit, Transsudat bzw. Exsudat in das Lumen der Paukenhöhle strömt. Dieses wässrige Ergußmedium zeigt auch biochemisch große Ähnlichkeit mit

Blutserum und Lymphflüssigkeit (Juhn et al., 1971 Tönder et al., 1971).

Unterdruck im Paukenlumen, Schädigung der Epithelzellen durch Ruptur ihrer Interzellularbrücken, starke Aufladung mit Extrazellularflüssigkeit führen offensichtlich zu einer Umdifferenzierung der Epithelzellen. In zunehmendem Maße wandeln sich die ursprünglich flachen Epithelzellen in hochprismatische, zilientragende Zellen um, andere wiederum lassen insbesondere in ihrem apikalen Zellbereich cytoplasmatische Neubildungen erkennen, die auf eine sekretorische Aktivität hindeuten. Eine Belüftung der Pauke im Frühstadium vor Beginn des epithelialen Umbaues bewirkt durch Verschluß der Interzellularspalten ein Sistieren des serösen Ergusses und verhindert sichtlich die Metaplasie des Epithels. In einem späteren Stadium werden die bereits angelaufenen Umbauvorgänge zwar aufgehalten, können aber nicht zu einer Rückbildung des bereits umdifferenzierten Epithels führen. Auch eine lang andauernde Belüftung hat jetzt keinen Einfluß mehr auf die neuen Schleimhautverhältnisse.

Verschiedene Untersuchungen menschlicher Schleimhauterkrankungen des Mittelohres, beispielsweise beim idiopathischen Hämatotympanon (Arnold & v. Ilberg, 1974) oder bei der otosklerotisch veränderten Mittelohrschleimhaut geben zu erkennen, daß eine alleinige Lymphostase im Subepithel, die mit einer starken Bindegewebsvermehrung und Einengung der extrazellulären Lymphbahnen einhergeht, offensichtlich ebenfalls bestimmte Epithelveränderungen bewirkt: daher kommt es an verschiedenen Stellen der Mittelohrschleimhaut zu inselförmigen Ansammlungen von kinozilientragenden, hochprismatischen Zellen. Schleimzellen jedoch, wie sie als typisch für ein lang anhaltendes Serotympanon oder Mucotympanon bekannt sind, werden bei diesen Erkrankungen nicht nachgewiesen. Das Auftreten von schleimproduzierenden Zellen im Mesotympanon bei chronischem Paukenerguß würde nach unseren Befunden ausschließlich eine Folge des chronischen Reizzustandes (erhöhter Unterdruck in den Mittelohrräumen, starke Flüssigkeitsaufladung der Epithelzellen) sein, wogegen kinozilientragende Zellelemente ihre Entstehung offensichtlich auf mehrere Faktoren zurückführen lassen.

Injiziert man zu einem Zeitpunkt, wo sich das Epithel bereits umdifferenziert hat und eine neue Funktion übernommen hat, Thoriumdioxyd in den Liquor, so kann dieses nicht wie üblich bis zum Epithel der Mittelohrschleimhaut vordringen, sondern hält sich infolge der erheblichen subepithelialen Fibrosierung nur noch in schmalen Lymphbahnen in der Tiefe der Submucosa auf. Diese submukösen Veränderungen, welche sowohl bei den experimentellen Untersuchungen beim Meerschweinchen wie auch bei den menschlichen Schleimhautproben deutlich wurden (die enorme Verbreiterung des subepithelialen Raumes, die bindegewebige Zunahme und die damit verbundene Einengung der ursprünglich weiten Extrazellularräume) sind die Erklärung dafür, daß bei zusätzlichen bakteriellen Infektionen, die sich ja klinisch häufig bei chronisch schleimproduzierenden Mittelohren einstellen, so selten eine Überleitung zum Labyrinth vorkommt. Offensichtlich stellt das aktiv schleimproduzierende Epithel mit seinem Oberflächenschleimfilm und der Kinozilienbewegung (Lim et al., 1972) zusammen mit dem stark bindegewebig verdichteten subepithelialen Raum eine ausgezeichnete Barriere gegen eindringende Keime dar. Hinzu kommt die erstaunliche Fähigkeit der Fibrozyten, sich sehr schnell auf verschiedenartige Reize einzustellen und Makrophagentätigkeit oder histiozytäre Aufgaben zu übernehmen (Arnold & v. Ilberg, 1974). Nach Untersuchungen von Tomasi et al. (1968) und Mogi et al. (1973) enthält der Schleim der umgebauten Epithelzellen reichlich lokale Immunglobuline, so daß die „Schutzwirkung" des neu gebildeten Epithels zusätzlich erhöht wird.

SUMMARY

1. Tubal obstruction causes a rapid rise in transepithelial cytopempsis. The squamous epithelial cells show numerous vesicles carrying subepithelial fluid (extracellular fluid) to the middle ear cavity. 24 hours following tubal obstruction widespread rupture of the epithelial junctions can be observed. Subepithelial fluid, consisting of

(1973) enthält der Schleim der umgebauten Epithelzellen reichlich lokale Immunglobuline, so daß die „Schutzwirkung" des neu gebildeten Epithels zusätzlich erhöht wird.

SUMMARY

1. Tubal obstruction causes a rapid rise in transepithelial cytopempsis. The squamous epithelial cells show numerous vesicles carrying subepithelial fluid (extracellular fluid) to the middle ear cavity. 24 hours following tubal obstruction a widespread rupture of the epithelial junctions can be observed. Subepithelial fluid, consisting of

lymphfluid, transudate and later exudate, enters the middle ear cavity without passing a cellular barrier

2 Long lasting negative pressure provoces a cellular differentiation (metaplasia!) of the formerly squamous epithelium to a high cylindric cell layer with new func tions cillary movement and secretory activity

3 Ablation of the tympanic membrane to expose the middle ear to air after 2–4 days, causes a stop in the epithelial differentiation but no regeneration to the nor mal histological flat formation

4 Studies of samples of human middle ear mucosa in serous otitis or sero-mucous otitis show exactly the same results as during the different stages of our animal experiments.

SIMULTANEOUS APPLICATION OF ELECTRONYSTAGMOGRAPHY (ENG) AND PHOTOELECTRONYSTAGMOGRAPHY (PENG) IN THE CASE OF THERMAL LABYRINTH EXAMINATION[1]

J Wilke K. H Gramowski and H Gobsch

From the Throat Nose-Ear-Clinic of the Medical Academy Erfurt DDR

Abstract At examination of normal persons, the ENG registration method was compared with that of PENG Special examinations were executed with regard to the behaviour of the beat rates during the culmination phase of thermal labyrinth reactions by using each of both registering methods. By synchronous recording of PENG and ENG it was possible to settle the discrepancy of the greater number of beats in ENG compared with those of PENG while the examinations were executed at different times. The PENG-method does not exclude an optical fixation due to the necessary interior illumination, and thus results in a retarding of the reaction and smaller beat rates. This fact should be considered when comparing the results of ENG and PENG

In order to carry out nystagmus recordings, we have applied both the ENG and the PENG methods. By registering the thermal labyrinth reactions of normal persons, we pointed out that in the electronystagmogram (ENG) the number of the nystagmus beats was greater than in the photoelectronystagmogram (PENG) it must be noted that registration was not executed simultaneously but in sequence Due to the greater number of beats in ENG than in PENG the problem again arose where on application of ENG potential variations could also be retarded in connection with the occurrence of genuine nystagmus. Although they give the impression of being nystagmus beats in the recording, they do not correspond to nystagmus occurrence in reality

We have already referred to the possibility (Gramowski, 1962, 1964 1965) that when applying the ENG method nystagmus-like disturbance variables sometimes may be recorded together with genuine nystagmus occurrence, thus making an exact evaluation questionable.

Frenzel s finding is worthy of mention in this regard. He was able to plot a "nystagmus curve when examining a bilaterally blind man whose right eye was enucleated and whose left eye was only a diminutive, contracted bulbus, so that the normal dipol relations did not exist.

When applying the PENG method, we can take it for certain that the nystagmus recordings we registered are an exact copy of the real movements of the eyes Thus it seemed obvious to examine the state of increased beat rates in the ENG by simultaneous PENG registration

Synchronous recording of thermal labyrinth reactions in normal persons by ENG and PENG enabled us to probe the ENG-method critically

MATERIAL AND METHODS

The comparative examinations were made with normal persons, i e otoneurologically healthy probands. The thermal irritation was caused with 20 ml of water at a temperature of 30 C During the examination the patient was in lying position with his head about 30 above the horizontal.

The application of the PENG method was made possible by using original PENG-spectacles, according to Gestewitz. This permits simultaneous measurement of both eyes and the registering of their movements the horizontal and the vertical components can be registered

[1] Devoted to Prof Fukuda on the occasion of his retiring as Director of the Department of Otolaryngology Gifu University School of Medicine.

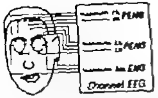

Fig. 1. Scheme for the synchronous recording of a ther mal labyrinth reaction (left ear was irrigated with 20 ml f water 30 C).

eparately The proband s eyes are illuminated hrough a red filter thus excluding fixation and dazzle, as far as is possible. By an infrared re flecting disc which is transparent and by optical means, the reflected light reaches the photoelec tric transducers. These have an internal resist ance of 10–20 kΩ, divided in 4 equal sectors, and provide each of the vertical and horizontal components of the eye movements with peak to-peak voltage

For registering the relatively small measured quantity of about 100 μV/30° of eye deviation, we have used an 8-channel EEG-device produced by VEB Messgerätewerk Zwönitz as previous ly recommended by Gestewitz (1965).

With this measuring device and after having carefully adjusted the optical system and cali brated the angle of view all clear registering of the nystagmus occurrence could be realized without further problems.

The routine recording of the ENG was done by an electronystagmograph from Tönnes (Frei burg/Breisgau). Some of the technical charac teristics of the ENG device differ considerably from those of the EEG device, and the record ing of ENG was therefore executed with the aid of the EEG device This was especially prac tised in order to obtain synchronous recording by ENG and PENG Concerning the above we state that due to the relatively small initial im pedance of the EEG device of about 800 kΩ,

Fig ENG recording during the culmination phase of thermal labyrinth reaction (left ear was irrigated with 20 ml of water, 30 C).

Fig 3. PENG recording during the *culmination* phase of thermal labyrinth reaction. Recording with proband's eyes open and illuminated by PENG red light. The pro*band was the same as in Fig. 2,* as also was the part of curve.

the ENG recording is rather problematic be cause the corneo-retinal potentials have the size of only 100 μV/30° of eye deviation. The required increase of ENG registering inevitably involves a higher interference level which, however can be limited sufficiently by a good arrangement of shielding and earthing. With the EEG device, the separate plottings of ENG and PENG raised almost no objects, though synchronous *recording was rather* problematic because, in addition to the preparations for PENG register ing, two electrodes had to be placed and fixed to the palpebral angles under the spectacles (Fig. 1).

With regard to the comparative examinations of the ENG and PENG methods, we generally restricted ourselves to recording the horizontal components of nystagmus.

RESULTS

The accompanying figures show the reaction curves registered at the examination of one proband. Fig. 2 is a part (culminations phase) of a thermal labyrinth reaction where the ENG-method was used. Registration was carried out

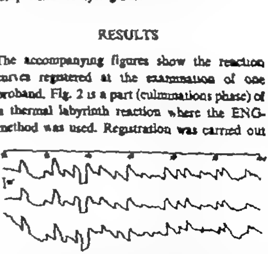

Fig 4 Synchronous recording of ENG–PENG during the culmination phase of thermal labyrinth *reaction* (left ear was irrigated with 20 ml of ater 30 C). Re cording with proband' eyes open and illuminated by PENG red light. Curve 1 PENG of right eye. Curve 2 PENG of left eye. Curve 3 ENG of both eyes. The proband was the same as in Figs. 2 and 3.

while the proband's eyes were open, but in a dark room. Thus any fixation was completely impossible. During the chosen interval of 30–60 seconds after having applied an irritation, 51 beats were registered (Fig. 2).

Fig. 3 shows another part of the nystagmus reaction in the same proband. The irritation modus was the same as in case shown in Fig. 2, namely irrigation on the left side with 20 ml H_2O of 30 C. The thermal labyrinth reaction, however, was recorded with the aid of the PENG spectacles *ad modum* Gestewitz. During the plotted time interval of 30–60 seconds, only 32 beats were registered, but it must be noted that this registration was executed in a dark room with the proband's eyes open, though the eyes were illuminated by red light as required by the PENG spectacles (Fig. 3).

Fig. 4 shows the synchronous recording of a thermal labyrinth reaction by PENG and ENG with the same proband and with the same irritation (Fig. 4). Here we have to state that in each ENG and in each PENG the same number of beats have been recorded (32 beats during the appointed time interval). Again, registering was executed with the proband's eyes open and under PENG-illumination. In ENG and PENG not only the number of beats, but also their form, are almost identical.

DISCUSSION

At first, the question arose whether the same beat rates could be received by simultaneous application of PENG and ENG in the course of a thermal labyrinth reaction. This question can be answered in the affirmative. The increased beat rates in the separate ENG (Fig. 2), in comparison with those in PENG (Fig. 3), under separate examination conditions, can be explained by extravestibular influences when applying the ENG method. With the ENG method (open eyes, dark room) a fixation of the eyes is almost impossible, whereas with the PENG method, a part fixation has to be taken into account from the very beginning. This part fixation will cause a retardation of the nystagmus reaction, and result in a smaller number of beats.

When comparing the results of examinations obtained by ENG and by PENG, one must consider that when applying the PENG-method, one has to put up with a certain influence from optical fixation.

The synchronous recording of nystagmus reactions by PENG and by ENG have proved that when registering with the aid of ENG, recordings are obtained which correspond to those of PENG, provided that the same recording conditions that are required in case of PENG application are applied. This statement by no means negates the critical hints concerning the ENG method (Gramowski, 1964, 1965; Jongkees, 1965; Meighian & Waldecker, 1961; Schaffrath, 1965). Nevertheless, when analysing ENG recordings, foreign potentials such as disturbance variables and possible sources of error have to be considered, and thus the interpretation of ENG results is problematic if it is done by inexperienced colleagues.

In the case of PENG application, there are no modifications in the nystagmus recordings caused by foreign potentials of different origin, though a certain rate of nystagmus retarding optical fixation cannot be excluded. If there is any doubt concerning the interpretation of ENG-curves, it is useful to carry out a synchronous recording by ENG–PENG.

ZUSAMMENFASSUNG

In Untersuchungen an Normalpersonen wurde das ENG mit dem PENG-Registrierverfahren verglichen. Speziell untersucht wurde das Verhalten der Schlagzahlwerte während der Kulminationsphase thermischer Labyrinthreaktionen bei Anwendung beider Registrierverfahren. Durch synchrone Aufzeichnung des PENG und des ENG konnte die Diskrepanz zwischen den höheren Schlagzahlen im ENG gegenüber PENG bei zeitlich getrennten Untersuchungsgängen geklärt werden. Bei der Anwendung des PENG-Verfahrens ist eine optische Fixation infolge der notwendigen Innenbeleuchtung nicht auszuschließen, wodurch eine Hemmung der Reaktion und daher geringere Schlagzahlwerte bei diesem Verfahren auftreten. Diese Tatsache sollte beim Vergleich von ENG- und PENG-Ergebnissen berücksichtigt werden.

THE EFFECT OF GRAVITY ON GALVANIC NYSTAGMUS IN RABBITS

T Swaak and W J Oosterveld

From the Department of Otolaryngology University of Amsterdam Amsterdam, The Netherlands

Abstract The effect of gravity on a galvanic nystagmus provoked in rabbits was investigated. Weightlessness increased the amplitude but decreased the frequency as well as the speed of the nystagmus. During continuous galvanic stimulation the provoked nystagmus disappeared spontaneously after a period of 60-120 seconds. Weightlessness was able to arouse this nystagmus again. An explanation of this phenomenon might be that galvanic nystagmus undergoes a modifying effect from the vestibular maculae and their state of stimulation.

Galvanic stimulation of the ear can provoke nystagmus (Brünings, 1911). This stimulation can be performed in several ways (Bellens, 1950) The size of the electric power required for the elicitation of galvanic nystagmus depends strongly on the method of stimulation If this method of stimulation is bipolar bi-auricular the necessary strength of the electric current is the lowest With galvanic stimulation in humans Hennebert (1950) found that at least 2-3 mA was necessary to elicit nystagmus This is in accordance with the findings of Hahn & Menzio (1966), however Pfaltz & Richter (1965) described a galvanic nystagmus in humans when they were stimulated with a current of 1-2 mA only

A galvanic nystagmus starts with an eye deviation to the side of the anode Stimulation with a pulsating galvanic current provokes a sinusoidal eye movement which oscillates in direct relation to the frequency of the pulsating current The amplitude of the eye deviation is related to the strength of the electric current A parallel swing gives similar eye movements to the subjects

In a previous study we described that—when both methods of stimulation are applied at the same time—the effects of both stimulations are summated algebraically (Swaak 1974) (Fig. 1)

In order to provoke a galvanic nystagmus in rabbits, a direct current of at least 1-5 mA must be applied The nystagmus caused in this way extinguishes within 60 seconds. In order to provoke a nystagmus with a constant frequency and a duration of more than 60 seconds, the current must be at least 10 mA.

The aim of this study is to investigate the effect of gravity on galvanic nystagmus in rabbits

METHODS

Experiments were performed in four rabbits. These rabbits were purebred laboratory animals (hollanders) with a weight of about 2 000 g each. In order to immobilize the animal it was tied to a rabbit holder and strapped with bandages.

Needle electrodes for the galvanic stimulation were applied in such a way that the stimulation could be given bipolar bi-auricularly The equipment for photonystagmography was mounted on the rabbit holder in such a way that movements of the left eye could be recorded (Fig. 2). Photonystagmography is the method of choice for galvanic nystagmus, since a galvanic current has a disturbing effect on electronystagmographic recordings. An electric current of 5-10 mA was applied in order to elicit a galvanic nystagmus. Increased g values, as well as weightlessness were evoked in an airplane Fokker F27 of the Royal Dutch Airforce As described in previous papers (Oosterveld, 1969) weightlessness could be achieved in periods from 5 up to 12 seconds when the airplane was performing

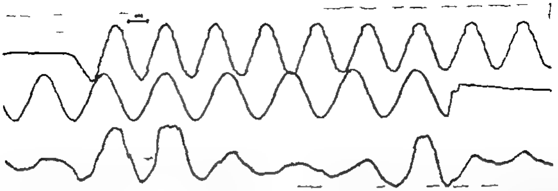

Fig. 1. A rabbit is stimulated by both an oscillating linear acceleration and an oscillating galvanic current. The oscillation times of both stimulations differ a little. The oscillating linear acceleration is applied by means of parallelswing. The rabbit is swung sideways. The recordings represent: (1) the movements of the parallelswing, (2) the sinusoidally oscillating galvanic current, (3) eye movements of the rabbit in the vertical plane.

parabolic flight. The weightless periods were preceded as well as followed by periods of approximately 10–15 seconds during which the g-load in the Z axis was increased up to 2.5 g.

Galvanic nystagmus was provoked in periods during which the galvanic nystagmus remained constant in speed and frequency. These periods lasted up to 120 seconds. In each period several paraboles were flown. With each rabbit the experiments were flown several times.

RESULTS

In the first period with increased g-value in the pull-up of the parabola the galvanic nystagmus showed an increase in frequency and speed

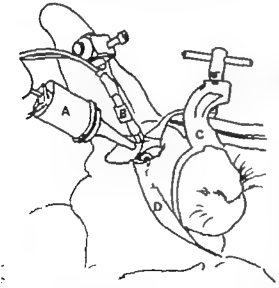

Fig. 2. (A) Infrared light source, (B) probe for photonystagmography, (C) rabbit holder, (D) ropes and clamp hooks keep the eye open.

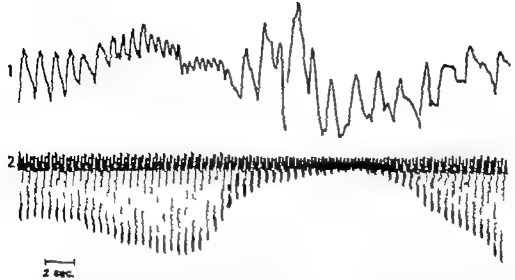

Fig 3 The effect of g-loading on galvanic nystagmus. The recording of the left eye of the rabbit is represented by 1 The g-load in the Z-axis is shown in curve 2. Before the weightless period the g load increases to 2 g. As soon as the value of g goes up the frequency of the nystagmus increases, while the amplitude decreases. In weightlessness the frequency decreases, while the amplitude increases.

(Fig. 3). In the weightless interval in the push over the frequency of the nystagmus decreased but the amplitude increased. In the second period with increased g, in the pull-out of the parabola, the galvanic nystagmus showed up again.

The increase as well as the decrease in nystagmus frequency and amplitude seize was found to be without any measurable latency

If weightlessness was introduced during galvanic stimulation but after the nystagmus had

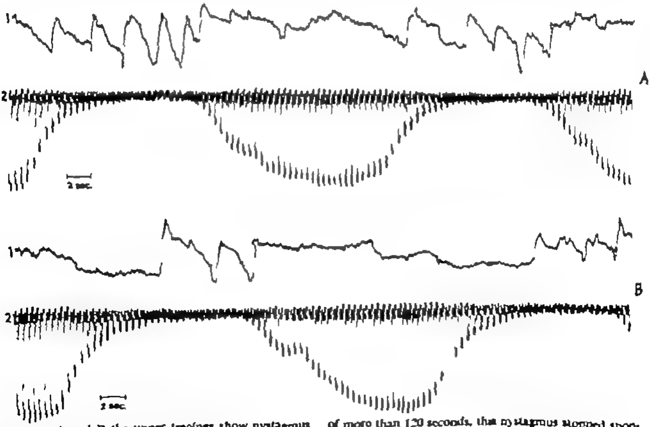

Fig 4 In A and B the upper tracings show nystagmus beats which appeared during weightlessness in two rabbits. After galvanic stimulation had been applied for a period of more than 120 seconds, that nystagmus stopped spontaneously In the period of weightlessness the nystagmus reappeared.

stopped (which happens 60–120 seconds after the onset of acceleration) the galvanic nystagmus reappeared (Fig. 4). The increasing g in the pull-out of the parabola made it fade away again. In other experiments performed in the rabbits no nystagmus could be elicited by differences in the g-load if galvanic stimulation had not been given before.

CONCLUSION

In a previous study we proved that weightlessness as well as increased g-values have a strong effect on positional alcohol nystagmus (Oosterveld, 1970).

Increase of g-value enhances the speed of the slow component of PAN. Just after PAN has disappeared, increase of the g-values makes the nystagmus reappear (Oosterveld, 1969).

In weightlessness PAN I as well as PAN II fade away. Similar results were found for the effect of gravity on caloric vestibular nystagmus. Rotational nystagmus elicited in the weightless state in rabbits proved to increase in amplitude and frequency. The effect of increased gravity on galvanic nystagmus is in agreement with this, in contrast with the observation on caloric and alcohol nystagmus, weightlessness can bring a galvanic nystagmus back.

An explanation of this phenomenon might be that galvanic nystagmus undergoes a modifying effect from the vestibular maculae and their state of stimulation. When the maculae are not stimulated by any gravitational acceleration, the vestibular system increases its responses to a rotation acceleration. The same seems to happen to the phenomen of the galvanic stimulation.

J B Baron N Ushio M Gregoric, T Mano J Noto G Bizzo P M Gagey J C Bessineton et M Pacifici

Centre Psychiatrique Sainte-Anne Paris France

Lors du Second Symposium International de Posturographie de Smolenice, après la communication de G Bizzo (1973) sur les stimulations galvaniques labyrinthiques et celle de P M Gagey (1973) sur les variations de tonus au niveau des membres inférieurs induits par les mouvements de la tête et des yeux, nous avons été amenés à discuter avec les professeurs V S Gurfinkel (1973)[1] et M Alexeef (1973)[1] sur les rapports existant entre la direction des déplacements de l axe du corps à la suite de stimulations galvaniques labyrinthiques et le changement de position de la tête et des globes oculaires. Nous regrettions alors dans cette discussion l absence du professeur T Fukuda (1957) dont les travaux dans ce domaine font autorité reprenant sous un aspect original les travaux fondamentaux de Magnus (1924) sur les réflexes toniques posturaux.

A mon retour en France, séduit par ce thème de recherches, mon équipe à laquelle s était associée N Ushio[2] déjà sensibilisé à ces problèmes par ses maîtres M Hinoki (1971), T Fukuda & D Nonaka (1954) se mettait au travail sur cette étude Sur ces entrefaits deux neurologues T Mano[3] et M Gregoric[4] étant venus dans mon service pour un bref séjour de travail se joignaient à nous, apportant leur expérience des réflexes T et H

MATERIEL ET METHODE

7 jeunes pompiers volontaires, d âge variant de 18 à 20 ans, ont participé à l expérience dans les conditions suivantes

1 *Etude statokinésimétrique*

Le sujet debout sur la plateforme détectrice du statokinésimètre dans une pièce obscure regarde 1) soit droit devant lui une barre fluorescente placée dans le plan médian de son polygone de sustentation 2) soit un point lumineux de 2 mm placé à un mètre à 45

Il reçoit à travers une électrode mastoïdienne positive et une électrode controlatérale négative au poignet un courant galvanique de 0 5 mA 6 stimulations rectangulaires de 4 secondes chacune, séparées stochastiquement par des intervalles de 10 à 15 secondes sont appliquées pour chaque essai La stimulation déclenche le balayage d un analyseur multicanaux à mémoire fonctionnant comme un moyenneur qui enregistre les déplacements stabilographiques Avant/

[3] Assistant de neurologie à Nagoya, Japon.
[4] Assistant de neurologie à Ljubljana, Yougoslavie.

Arrière et Gauche/Droite des informations provenant du statokinésimètre.

Les conditions expérimentales sont les suivantes.

A. Le sujet à la tête fixe (plan sagittal perpendiculaire à l'horizontale). Il regarde la barre lumineuse.

B. Le sujet à *la tête mobile (plan sagittal tourné à 70° sur l'horizontale). Il ne regarde plus la barre lumineuse mais tourne sa tête soit à* droite soit à gauche de telle sorte que la mastoïde portant l'électrode positive se trouve soit vers l'avant soit vers l arrière.

C. Le sujet à la tête fixe (plan sagittal) perpendiculaire à l'horizontale). Il regarde le point lumineux situé soit du même côté soit du côté opposé à la mastoïde portant l'électrode positive.

D. Le sujet à la tête mobile (plan sagittal incliné de 45° sur l'horizontale). Il regarde la barre lumineuse et incline sa tête soit du même côté soit du côté opposé à la mastoïde portant l'électrode positive.

Dans ces différentes conditions expérimentales, une première série d examens est pratiquée le pôle positif placé à la mastoïde droite, une seconde série, le pôle positif à la mastoïde gauche.

II. *Etude du réflexe H et T*

L étude du *réflexe H se fait* avec un stimulateur et un électromyographe DISA (2 canaux, type 14 1 21).

L étude du réflexe T se pratique a ec un marteau mobile sur une potence équipé d un accéléromètre *déclenchant le balayage d un* oscilloscope (*TEKTRONIX 5103 N*).

Les conditions expérimentales sont les suivantes le sujet étant couché *sur le ventre*

A. La tête fixe (plan sagittal perpendiculaire à l'horizontale), il regarde soit droit devant lui, soit à droite puis à gauche à 45

B. La tête mobile (plan sagittal tourné à 45 *sur l'horizontale*), il tourne la tête à droite puis *à gauche en regardant dans la direction du dé*placement *céphalique.*

Chaque essai est pratiqué sur la *jambe droite* puis sur la jambe gauche.

Pour le réflexe T 10 stimulations sont appliquées et sommées. Pour le réflexe *H*, 10 *groupes* de 2 stimulations *séparées de 50, 100*, *150*, 200, 300 ms sont *délivrées et sommées.*

RESULTATS

I *Etude statokinésimétrique*

1 *Dans la situation A.* La stimulation galvanique électrique labyrinthique provoque un déplacement latéral du centre de gravité du corps du côté du pôle positif (Fig. 1A). Nous avons montré antérieurement (Bizzo & Baron, 1972) que ce déplacement était proportionnel à l'intensité du courant pour des valeurs comprises *entre* 0,25 *et* 0 75 mA. *La stimulation provoque un effet facilitateur du tonus des muscles abducteurs de* la *cuisse, tenseur du fascia lata homolatéral* au pôle positif Ce qui semblerait prouver l'existence d'une voie *fonctionnelle vestibulo-spinale jouant* sur le motoneurone des abducteurs, adducteurs des membres inférieurs et particulièrement du tenseur du fascia lata.

2. *Dans la situation B* La stimulation galvanique électrique labyrinthique provoque un déplacement antérieur ou postérieur du centre de gravité du corps du côté du pôle positif (Fig. *1 B). La rotation de la tête changeant la répartition tonique entre les muscles nucaux droits* et gauches ainsi que sur leurs tendons et les ligaments de l'articulation nucale change la direction du déplacement du corps induit par la stimulation. C'est le tonus des muscles fléchisseurs ou extenseurs des membres inférieurs qui est *facilité* bilatéralement suivant la position de la tête ce qui semblerait mettre en évidence une voie *fonctionnelle* nuco-spinale jouant sur *les différents motoneurones* des muscles fléchisseurs, *extenseurs des membres inférieurs.*

3. *Dans la situation C La stimulation galvanique électrique labyrinthique provoque un dé*placement latéral du centre de gravité du corps d une amplitude inférieure à celle obtenue lorsque la tête est droite (situation A) (Fig. 1C). La déviation des globes oculaires change la *répartition* tonique entre les muscles moteurs *oculaires abducteurs*, adducteurs droits et *gauches ainsi qu'entre* leurs tendons entraînant

une diminution du déplacement du centre de gravité du corps d autant plus marquée que la déviation des globes oculaires est opposée au pôle positif C'est le tonus des muscles abduc teurs, adducteurs, des membres inférieurs qui est inhibé en fonction des variations de tonus des muscles moteurs oculaires ce qui semble mettre en évidence une voie fonctionnelle oculo-motrice spinale jouant sur les différents moto-neurones des muscles abducteurs, adducteurs des *membres inférieurs.*

4 *Dans la situation D* La stimulation galva nique électrique labyrinthique provoque un dé placement latéral *du centre de gravité du corps* d une amplitude inférieure à celle obtenue lors-que la tête est droite (situation A) (Fig. 1D) Cette diminution est d autant plus marquée que la déviation de la tête est opposée au pôle posi tif elle est soit inférieure à la situation C si la déviation de la tête est opposée au pôle positif soit supérieure si la déviation de la tête est du même côté que le pôle positif La déviation latérale de l axe de la tête change la répartition tonique entre les muscles profonds droits et gauches de la nuque ainsi qu entre leurs tendons et les ligaments de l articulation nucale entrai *nant une diminution dans le déplacement du* centre de gravité du corps. C'est le tonus des muscles abducteurs, adducteurs des membres *inférieurs qui est inhibé en fonction des varia* tions de tonus des muscles de la nuque droits et gauches ce qui semble mettre en évidence une voie fonctionnelle nuco-spinale jouant sur les différents motoneurones des muscles abducteurs, adducteurs des membres inférieurs.

Il est à noter que dans les situations B et D un maintien correct de la tête dans la position imposée est indispensable pour l obtention d une réponse caractéristique

II *Etude du réflexe H et T*

De nos résultats préliminaires il ressort que les réflexes H et T varient d amplitude en sens in verse suivant les variations de tonus des muscles nucaux et des muscles oculaires. Cette variation est asymétrique entre la jambe droite et la jambe gauche (Fig. 2)

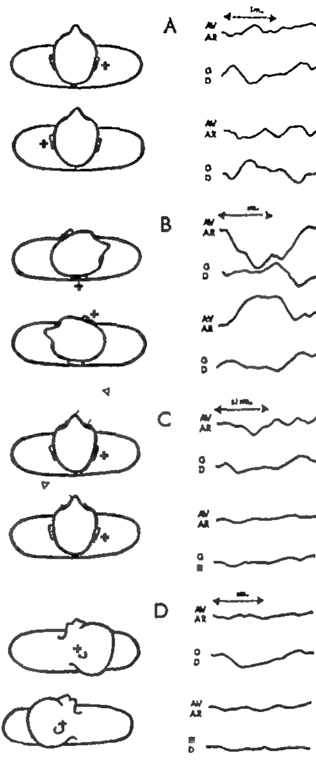

Fig 1 Etude statokinésimétrique des déplacements du centre de gravité du corps d un sujet recevant une sti-mulation gal anique labyrinthique de 0,5 mA pendant 4 secondes. (A) Stimulation seule; (B) stimulation rota-tion de la tête; (C) stimulation + rotation des yeux, (D) stimulation inclinaison de la tête

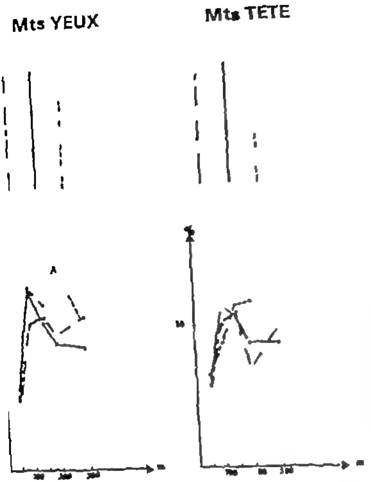

Fig. 2. Etude des réflexes *T* et H sur la jambe droite d'un sujet après mesure des résultats oscillographiques des réponses électromyographiques lorsque la tête ou les yeux sont tournés à droite (*D*, ---), à gauche (*G* — —), ou lorsqu'ils sont en position de repos (0, —).

CONCLUSION

ensemble de ces faits, dans nos conditions imentales, il résulte que dans la mise en et le maintien de la projection du centre ravité du corps à l'intérieur du polygone ustentation un certain nombre de systèmes ori-moteurs rentre en jeu.

) *un système vestibulo-spinal parfaitement* lu et bien isolé dans sa réponse à la stimulation galvanique intéressant le fonctionnement muscles abducteurs et adducteurs des membres inférieurs.

b) un système nuco-spinal concernant le fonctionnement des muscles abducteurs, adducteurs et fléchisseurs, extenseurs des membres inférieurs.

(*c*) un système oculo-spinal se rapportant au fonctionnement des muscles abducteurs, adducteurs des membres inférieurs.

Ces deux derniers systèmes modulent par leur effet facilitateur ou inhibiteur les réponses de la stimulation galvanique labyrinthique. Ils pourraient avoir comme point de départ soit les terminaisons annulospiralées musculaires soit des *organes golgiens tendineux ou rufiniens* ligamentaires.

Des études en cours permettent d'aborder le mode d'action de ces différents systèmes. L'étude des réflexes H et T lors des changements de la position de la tête ou des globes oculaires localiserait le point d'impact des voies nuco-spinale et oculo-spinale au niveau médullaire. Leur variation semblerait impliquer une action

une diminution du déplacement du centre de gravité du corps d autant plus marquée que la déviation des globes oculaires est opposée au pôle positif C'est le tonus des muscles abduc teurs, adducteurs, des membres inférieurs qui est inhibé en fonction des variations de tonus des muscles moteurs oculaires ce qui semble mettre en évidence une voie fonctionnelle oculomotrice spinale jouant sur les différents motoneurones des muscles abducteurs, adducteurs des *membres inférieurs.*

4 *Dans la situation D* La stimulation galva nique électrique labyrinthique provoque un dé placement latéral du centre de gravité du corps d une amplitude inférieure à celle obtenue lorsque la tête est droite (situation A) (Fig. 1 D) Cette diminution est d autant plus marquée que la déviation de la tête est opposée au pôle posi tif elle est soit inférieure à la situation C si la déviation de la tête est opposée au pôle positif soit supérieure si la déviation de la tête est du même côté que le pôle positif La déviation latérale de l axe de la tête change la répartition tonique entre les muscles profonds droits et gauches de la nuque ainsi qu entre leurs tendons et les ligaments de l articulation nucale entrai nant une diminution dans le déplacement du centre de gravité du corps. C'est le tonus des muscles abducteurs, adducteurs des membres inférieurs qui est inhibé en fonction des varia tions de tonus des muscles de la nuque droits et gauches ce qui semble mettre en évidence une voie fonctionnelle nuco-spinale jouant sur les différents motoneurones des muscles abducteurs, adducteurs des membres inférieurs.

Il est à noter que dans les situations B et D un maintien correct de la tête dans la position imposée est indispensable pour l obtention d une réponse caractéristique

TISSUE CULTURE OF THE ORGAN OF CORTI AND THE ISOLATED HAIR CELLS FROM THE NEWBORN GUINEA PIG

T. Yamashita and K. H. Vosteen

From the E.N.T. Department, University of Frankfurt am Main, BRD

Abstract. The organ of Corti and isolated hair cells from newborn guinea pig were cultured with the Rose chamber method. The hair cells could be maintained for more than 20 days after explantation when the organ of Corti was cultured as a whole, though the isolated hair cells swelled and degenerated within about 13 hours after explantation. By comparison between the tissue culture of the hair cells with the organ of Corti and isolated hair cell culture, the following conclusions were reached. (1) There are some functional correlations concerning the nutritional requirements and cell metabolism between the hair cells and the supporting cells in addition to the structural correlations. (2) There are no distinct fundamental differences between both inner and outer hair cells about their affectability as a single cell level.

Many investigations have been carried out in making clear the structures and functions of the inner ear. The first attempts have been done by morphological ways with the fixation and staining. Later the histochemical and electrophysiological approaches have played a great role to know the function of the inner ear. The application of electron-microscopical techniques have contributed considerably to our knowledge of the cytology of the inner ear. But the observations of the inner ear cells grown in tissue culture with phase-contrast microscopy might be also important from now on, because of dealing with real living cells without any fixation and staining.

The first successful attempt in cultivating the inner ear cells in vitro has been done by Fell (1928) using the chick embryo otocyst. Since Fell's report, many investigations have communicated various techniques for the in vitro development of the otocyst, but most of them have been done using the fowl embryo otocyst (Friedmann, 1956, 1959, 1961, 1968, 1969; Friedmann & Bird, 1961, 1967; Reinecke et al., 1960; McAlpine & Friedmann, 1963; Shambaugh & Orr, 1963; Iwai, 1964; Orr, 1965, 1968; Kitano, 1968). Some works have been done with the mammalian otocyst (Maximow, 1925; Lawrence & Merchant, 1953; Sugawara, 1964; Van De Water & Ruben, 1971, 1973*a*; Van De Water et al., 1973*b*).

Owing to the special structure of the inner ear it is better to choose the material that is already well differentiated. There are few informations defining the in vitro development of the well differentiated mammalian inner ear. Shambaugh (1956) and Sugawara (1964) have investigated the in vitro development of Corti's organ of newborn cat. Iwai (1959) reported the in vitro development of the spiral ganglion of newborn rabbit. Recently Iwai et al. (1967) and Okano et al. (1971) showed some observations of the inner ear cells from newborn dog by tissue culture technique. There have been no report of any cultivation of the inner ear of newborn guinea pig in vitro.

The organ of Corti and isolated hair cells of the inner ear of newborn guinea pig have been cultivated in Rose chambers forcing the explant to grow in a thin flat layer suitable for phase-contrast microscopy.

MATERIAL AND METHODS

The experiments were carried out on 60 newborn guinea pigs only 1 and 2 days old. The animals were decapitated, the whole temporal bone was quickly dissected out of the skull using sterile technique, the bony wall of the cochlea was chipped away and the apical part of the membranous cochlear duct was removed from

directe sur le motoneurone α facilitatrice et sur la boucle γ inhibitrice au niveau médullaire ou vice versa.

Nous avons tenu a attirer l attention sur l importance des voies fonctionnelles vestibulo-oculo-nucales dans l activité tonique posturale orthostatique en insistant tout particulièrement sur ces deux dernières par le rôle qu elles jouent dans l équilibre. On ne doit pas négliger d examiner leur fonctionnement au cours de certains déséquilibres dont l étiologie vestibulaire n est pas en cause et ce sera tout particulièrement le cas au cours de certains déséquilibres inexpliqués du syndrome subjectif post-commotionnel des traumatisés crâniens et au cours de certaines intoxications. L étiologie tronculaire du déséquilibre intéressant les noyaux du III du IV du VI du XI et le noyau supraspinal devra être envisagée en l absence de localisation cérébrale ou cérébelleuse.

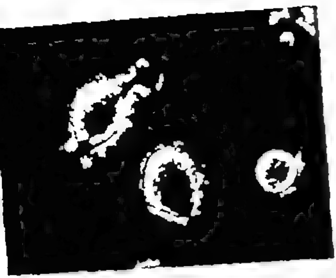

Fig. 2. Macrophages from the explant of the organ of Corti. Scale = 30 μm (a 7-day culture).

sessed one oval nucleus with several nucleoli and they had many granular materials of active motility in cytoplasm.

The outgrowth of fibroblasts from the explant of CORTI began within 1 day after explantation (DAE) and reached its peak on about 15 DAE, covering almost the whole surface of the cover glass. During 30 DAE, fibroblasts aggregated in groups and finally made several degenerating tissue mass on more than 40 DAE. Most of fibroblasts were thought to grow out from the layer of the thin endothelium of the basilar membrane, which was faced with the scala tympani and was of mesenchymal origin (Fig. 1).

(*b*) *Macrophages*. After 6 to 8 DAE, the isolated wandering cells of fair motility appeared in the sheets of outgrow epithelial cells or the outgrow fibroblasts layers from the explant of Corti, were highly amoeboid and could be seen to be phagocytic. They were so-called macrophages which were mostly round and spindle in shape, were mononucleate and had many granular materials and vacuoles various in size in the cytoplasm. They also had a transparent hyaline membrane which extended towards the outside of the cells (Fig. 2).

2. *Epithelial cells*

From 2 to 4 DAE, epithelial cells emerged as sheets of cells closely adherent to each other from the explant of CORTI and these outgrowths mainly came from the supporting cells, especially the Hensen's cells and cells of Claudius. The sheet of epithelial cells took place connecting to the outer margin of the explant, and on the outmost area of this sheet the fibroblasts layer grew extensively (Fig. 3).

In this period, the cytological characteristics of the epithelial cells appeared as polygon in shape, and showed one round nucleus with several small nucleoli at the periphery and a number of granular materials in the cytoplasm.

Generally speaking, *in the first stage, it is* possible to decide the origin of the outgrow epithelial cells, because the cells which emerge from the various tissues in fresh culture become altered as compared with their counterparts in the original tissue, and a little consideration of the normal histology of the various tissues of the body leads to the conclusion that the tissues of each organ differ morphologically much more in the arrangement of their cells than they do in the actual cell-type which they contain. In fact, also in this experiment, by daily observation on morphological specificity of each cells and cell arrangement, it was possible to distinguish the outgrow epithelial cells from Hensen's cells (*Fig. 4a*) and Claudius' cells (*Fig. 4b*) only in the first stage, because the fresh outgrow epithelial cells from Hensen's cells contained a few

Fig 1 Fibroblasts (*F*) from the layer of thin epithelium of basilar membrane (*EB*). The outgrow *epithelial cells* sheet (*E*). Original Hensen's cells (*H*). Scale in *a* = 50 μm. Scale in *b* = 30 μm (a 3-day culture).

the bony cochlea under the dissecting microscope For the tissue culture of the organ of Corti as a whole the organ of Corti with basilar membrane (CORTI) was separated from the membranous cochlear duct For the isolated hair cell culture the hair cell layers were again separated from another part of the organ of Corti with a fine scalpel and forceps.

The Rose chamber (Rose, 1958) was used which was formed of 2 large cover glasses, separated by a rubber gasket and held together by 2 metal plates and 4 screws. The explants were put on a cover glass and covered by a cellophane dialysis strip and the parts of the chamber were assembled. Nutrient fluid was then injected through the rubber gasket.

The following nutrient fluids were used in this study Medium A 50% human ascitis fluid 50% Gey's balanced salt solution 100 u/cc penicillin and 0.1% phenol red as a pH indicator Medium B 85% nutrient mixture F 10 (GIBCO*), 12.5% horse serum 2.5 fetal calf serum 100 u/cc penicillin and 0.1% phenol red. Both media showed encouraging results for the growth of the cells, but there was a slight difference between them medium B was better for the developing epithelial cells and medium A for mesenchymal cells. The nutrient fluid was changed as needed according to the pH indicator usually once every 4 days. The cultures were incubated at a temperature of approximately 37°C. Daily observations were made and photographed under a phase-contrast microscope

RESULTS

I Tissue Culture of the Organ of Corti as a Whole

1 Mesenchymal cells

(*a*) *Fibroblasts* Fibroblasts emerged as a loose network of cell from various sources of explant, all of which were however mesenchymal They showed spindle, polygonal or oblong cell bodys with the spindle-shaped process. Each cell pos

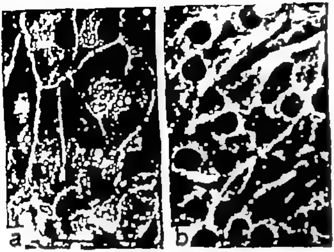

Fig. 4. Fresh outgrow epithelial cells from the Hensen cells (*a*) contain several lipid-like granules in the cytoplasm, and they appear a little longer in shape than the cells from the Claudius' cells (*b*). Scale = 30 μm (a 3-day culture).

Fig. 5. Normal outgrow of epithelial cells. Scale = 30 μm (a 5-day culture).

Fig. 6. Degenerating pattern of the outgrow epithelial cells. Scale = 30 μm (a 15-day culture).

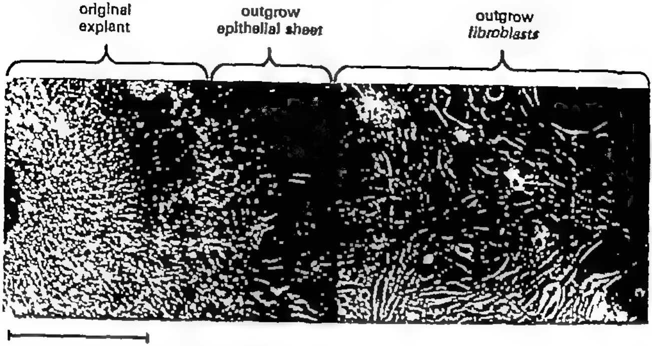

Fig 3 Typical figure of the cultivated explant of the organ of Corti. Scale = 200 μm (a 3-day culture).

lipid granules in the cytoplasm and were a little longer in shape than the cells from Claudius cells.

The alterations, however appeared to occur in steps, the cell form was gradually enlarged and the granular materials began to have movement which was not so active as in the case of fibroblasts (Fig. 5). In this period, it became impossible to distinguish between two of them.

Within 6 to 7 DAE, the formation of sheets of these outgrow epithelial cells reached its peak and they were maintained their "healthy condition till about 15 DAE and later many small (Fig. 6*a*) or a single large vesicle (Fig 6*b*) appeared in the cytoplasm as the process of degeneration.

During 5 to 7 DAE, several hair cells were found in these epithelial cell sheets in some cases of explants (Fig. 7). These hair cells were isolated from one another and did not form groups, and they were identified from another epithelial cells because of having the auditory hair as a morphological characteristic and being oval in shape. Through daily and detailed observations, it was noticed that the maintained original hair cells seemed pushed aside by new outgrow epithelial cells and finally isolated as foreign bodies" in the sheets of epithelial cells, and therefore it could be said that these hair cells observed in the culture should never be the outgrow cells developing from the hair cell origin. Even if the new epithelial cells could emerge from the hair cell origin in this experiment it was impossible to identify them morphologically under a phase-contrast microscope.

3 *The hair cells within the explant area*

Within the explant area, as early as 3 hours after explantation (HAE), both inner and outer hair cells began to swell more or less. Most of them reached their peak of swelling on about 12 to 15 HAE (Fig. 8) and returned to the normal form completely or incompletely within 3 DAE (Fig. 9), but some of them degenerated and did not recover. During these changes, the outer hair cells swelled more severely lost the arrangement more easily and were less successful to recover than the inner.

After 3 DAE, the pattern of changes of the hair cells depended upon whether the hair cells

Fig. 10. Well arranged and maintained outer hair cells covered by the tectorial membrane. Scale = 30 μm (a 20-day culture).

were covered with the tectorial membrane or not. The hair cells which were covered with the tectorial membrane had great resistance against degeneration and they remained unchanged or almost in original form for about 20 DAE (Fig. 10). The hair cells which were not covered with the tectorial membrane appeared disordered in arrangement, but some of them were maintained with the auditory hair for 15 DAE, though they showed *half swelling in appearance* (Fig. 11).

II. *Isolated Hair Cell Culture*

When the organ of Corti was cultured as a whole, it was difficult to observe the hair cells as a total figure because of the special three-dimensional structure of the organ of Corti.

By *separating the layers of Hensen's cells* which were easily distinguished for containing the lipid granules in the cytoplasm from the membranous cochlear duct, the single hair cell layer *or single hair cells could be easily obtained* with Hensen's cell layer together from another part of the organ of Corti. These single hair *cell or single hair cells which* were in contact with the Hensen's cell layer were cultured in the similar manner as normal tissue culture and observed in time-lapse under a phase-contrast microscope.

The single hair cell layer or single hair cells

were covered with the tectorial membrane or not. The hair cells which were covered with the tectorial membrane had great resistance against degeneration and they remained unchanged or almost in original form for about 20 DAE (Fig. 10). The hair cells which were not covered with the tectorial membrane appeared disordered in arrangement, but some of them were maintained with the auditory hair for 15 DAE, though they showed ball-swelling in appearance (Fig. 11).

II. *Isolated Hair Cell Culture*

When the organ of Corti was cultured as a whole it was difficult to observe the hair cells as a total figure because of the special three-dimensional structure of the organ of Corti.

By separating the layers of Hensen's cells which were easily distinguished for containing the lipid granules in the cytoplasm from the membranous cochlear duct, the single hair cell layer or single hair cells could be easily obtained with Hensen's cell layer together from another part of the organ of Corti. These single hair cell or single hair cells which were in contact with the Hensen's cell layer were cultured in the similar manner as normal tissue culture and observed in time-lapse under a phase-contrast microscope.

degenerated very quickly in vitro and could be classified roughly into 2 types by the changing of the cell body the swelling type and the atrophy type

(a) Swelling type

Just after explantation, the outer hair cells were cylindrical in shape with a round base On the apical surface they carried an annular reticular lamina with auditory hair The nucleus which was round in shape and had small nucleoli at the periphery was situated closer to the basal pole of the cell. The cytoplasm had granular materials especially in the apical and the basal part.

The inner hair cells were also cylindrical in shape but the length was shorter and the width was wider than the outer hair cells just after explantation The cytoplasm had much granular materials on an average The nucleus the reticular lamina and the auditory hair were just like those of the outer hair cells

The cytoplasm and the nucleus of both inner and outer hair cells of this type showed no staining by Erythrocin B (Phillips, 1959) So the cell and cell membrane were thought to be "living" and healthy

The granular materials in the cytoplasm had no movement till the cell ruptured.

In most cases of the outer hair cells, from 1 or 2 HAE, the cell body began to swell in the basal part. On 5 to 6 HAE, the swelling was at the peak and the cell body became nearly perfectly round without the part of the reticular lamina On more than 8 to 10 HAE, the cell ruptured and took way to atrophy (Fig 12)

In some cases of the outer hair cells, the swelling began from the middle part of the cell body and the atrophy came gradually before the swelling had reached its peak (Fig. 13*a*).

In all cases of the inner hair cells, the swelling began from 1 HAE, reached its peak within 5 to 6 HAE and the rupture and atrophy came later (Fig. 13*b*).

About both hair cells, till the rupture of the cells, the nuclei had such a slight change that small vesicles appeared at the periphery of nuclei but after the rupture the nuclei themselves also swelled and increased the diameter especially in the inner hair cells (Fig. 14). The reticular lamina and the auditory hair showed no changes after the rupture of the cell.

(b) Atrophy type

Just after explantation the cell membrane of the outer hair cells of this type showed a little atonic in the basal part which had been in contact with the cells of Deiters

In the cytoplasm the granular materials which were thought to be mitochondria and lysosomes had very rapid movement, that might be so-called "Brownian movement"

Fig. 15. Outgrow epithelial cells from the isolated Hensen's cells. Scale = 30 μm (a 5-day culture).

The cytoplasm and nucleus were well stained by Erythrocin B. So these cells were thought to have already some changes in the cell membrane by mechanical damages during the cultivating procedure.

With the lapse of time, the cells of this type gradually became atrophic, the granular materials tended to increase in number and small or large vesicles appeared in the cytoplasm. Within 13 HAE, the "Brownian movement" stopped and the cell became smaller in shape (Fig. 13c).

About the Hensen's cells, after 3 to 4 DAE, the new epithelial cells came out of the separated Hensen's cell layer and were maintained for more than 3 weeks in vitro (Fig. 15).

It must be mentioned that the isolated single hair cell layer or single hair cells degenerated almost perfectly only within 13 HAE, though the separated Hensen's cell layer which was explanted at the same time with the hair cells developed and was maintained for 3 weeks.

DISCUSSION

In this experiment the hair cells were maintained in vitro for more than 20 DAE, but the outgrowth of the epithelial cells from the hair cell origin could not be identified, though the outgrowth of the epithelial cells from the supporting cells of the organ of Corti were extensive. In some cases, the hair cells were found in the sheets of outgrow epithelial cells on 6 to 7 DAE, maintained for about 2 days and later degenerated. So these hair cells must be the original ones themselves and not the now outgrew epithelial cells from the hair cell origin. Though Sugawara (1964) reported the outgrowth of the epithelial cells from the hair cell origin using newborn cat, Shambough failed to distinguish exactly the outgrow epithelial cells from the inner ear of newborn cat from another epithelial structure, such as skin, respiratory mucosa or gastrointestinal mucosa (Reinecke et al., 1960). Iwai et al. (1967) also reported using newborn dog that the hair cells did not develop, though they were maintained for 2 weeks. So it may be possible to say that the well differentiated hair cells as in case of nervous cells cannot develop any more in vitro, in contrast with the supporting cells.

Within the explant area, the hair cells showed the morphological degenerative changes such as swelling at an early stage of culture, but after several days some of them recovered almost perfectly especially in the inner hair cells. Several electrophysiological investigations (Wever et al., 1949; Perlman & Kimura, 1959; Konishi et al., 1961) showed that the functions of the hair cells which had once come down by anoxia could recover when oxygen was supplied again. Yamashita et al. (1973) also reported the similar findings with the histochemical approach. Iwai

degenerated very quickly in vitro and could be classified roughly into 2 types by the changing of the cell body the swelling type and the atrophy type

(a) Swelling type

Just after explantation the outer hair cells were cylindrical in shape with a round base On the apical surface they carried an annular reticular lamina with auditory hair The nucleus which was round in shape and had small nucleoli at the periphery was situated closer to the basal pole of the cell The cytoplasm had granular materials especially in the apical and the basal part.

The inner hair cells were also cylindrical in shape, but the length was shorter and the width was wider than the outer hair cells just after explantation. The cytoplasm had much granular materials on an average The nucleus, the reticular lamina and the auditory hair were just like those of the outer hair cells.

The cytoplasm and the nucleus of both inner and outer hair cells of this type showed no staining by Erythrocin B (Phillips, 1959) So the cell and cell membrane were thought to be "living" and "healthy"

The granular materials in the cytoplasm had no movement till the cell ruptured

In most cases of the outer hair cells, from 1 or 2 HAE, the cell body began to swell in the basal part. On 5 to 6 HAE, the swelling was a the peak and the cell body became nearly perfectly round without the part of the reticular lamina. On more than 8 to 10 HAE, the cel ruptured and took way to atrophy (Fig. 12).

In some cases of the outer hair cells, the swelling began from the middle part of the cell body and the atrophy came gradually before the swelling had reached its peak (Fig. 13*a*)

In all cases of the inner hair cells, the swelling began from 1 HAE, reached its peak within 5 to 6 HAE and the rupture and atrophy came later (Fig. 13*b*)

About both hair cells, till the rupture of the cells, the nuclei had such a slight change that small vesicles appeared at the periphery of nuclei but after the rupture the nuclei themselves also swelled and increased the diameter especially in the inner hair cells (Fig. 14) The reticular lamina and the auditory hair showed no changes after the rupture of the cell.

(b) Atrophy type

Just after explantation the cell membrane of the outer hair cells of this type showed a little atonic in the basal part which had been in contact with the cells of Deiters.

In the cytoplasm the granular materials which were thought to be mitochondria and lysosomes had very rapid movement that might be so-called "Brownian movement

ments were observed in the cytoplasm of the hair cells when they were intact and actively living. However the extensive granular movements like "Brownian movement" appeared when the cell membrane of the hair cells was already damaged more or less such as in the atrophy mentioned above or the swelling type at the maximal swelling. The following can be thought. Originally the cytoplasm of the hair cells is so-called "gel" condition and it has no granular movement. By the change of the permeability of membrane according to the damage of cells, the cytoplasm changes from "gel" to "sol" and the unphysiological granular movement like "Brownian movement" appears. So, in other words, it can be said that the granular movements in the cytoplasm is a sign of the membrane damage in case of the hair cells.

In this experiment, the outer hair cells were easily affected by the changes of circumstances in culture than the inner when the organ of Corti cultivated as a whole. Much greater differences are found in the behavior pattern of both hair cells in other experimental conditions. Davis (1953) found that the outer hair cells were more easily injured than the inner by sounds of considerable strength. Hawkins & Lurie (1962) showed that the inner hair cells suffered injury after administration of streptomycin. Nevertheless, the outer hair cells are always more sensitive to drugs than the inner (Ward & Fernandez, 1961; Beck & Krahl, 1962; Engström & Kohonen, 1965). They are also easily damaged by circulatory arrest (Kimura & Perlman, 1956) and anoxia (Yamashita & al., 1973). On the contrary when the isolated hair cells were cultivated, both hair cells had not any great differences in their behavior pattern. In the present experiment, both inner and outer hair cells swelled and degenerated similarly. From these findings, the differences in the behavior pattern of both hair cells mentioned above are thought to depend on each different standpoint in the structure of the organ of Corti which, for example, the outer hair cells are surrounded at the sides largely by intercellular fluid in contrast to the inner (Guild, 1932). Though electron-microscopical and histochemical investigations offer some informations about the dissimilar structural differentiation of these cells (Engström & Wersäll, 1958; Iurato 1961), it can be said that as a single cell level there are no fundamental differences between both hair cells about their affectability at least in vitro.

ZUSAMMENFASSUNG

Gewebekulturen von Haarzellen lassen sich entweder durch Inkubation des gesamten Cortischen Organes oder durch Züchtung isolierter Haarzellen gewinnen.

Bei Explantation des gesamten Cortiorganes beträgt die Überlebenszeit der Haarzellen mehr als 20 Tage, jedoch ist eine laufende Beobachtung des Auswachsens der Epithelzellen dabei nicht möglich. Bei Kulturen von isolierten Haarzellen kommt es schon innerhalb von 13 Stunden zur Degeneration und zur Schwellung der Zellen.

Durch Vergleich von gezüchteten Haarzellen aus dem gesamten Cortischen Organ einerseits und von Kulturen isolierter Haarzellen andererseits kommen wir zu folgenden Schlußfolgerungen: 1) Für die Ernährung und den Stoffwechsel der Haarzellen ist die intakte Struktur der Stützzellen erforderlich. 2) Bei Kulturen von isolierten Sinneszellen unterscheiden sich innere und äußere Haarzellen nicht in ihrer Empfindlichkeit gegen Zellschädigungen.

(1964) showed morphologically in vitro the recovery of the nervous tissue which had once degenerating process. The investigations about the recovery of once damaged hair cells are of interest for the therapy of the inner ear pathology Furthermore it is also important to know whether a complete recovery is possible and to what extent of damage would interfere with a reasonable recovery However the present observation did not provide enough information of these things.

For long time there have been many discussions about the correlation between the tectorial membrane and the auditory hair of the hair cells The present data showed that the hair cells covered with the tectorial membrane could be maintained for longer time than those not covered with it in the explant area It may be said that the tectorial membrane contributes to the maintenance of the hair cells to some extent

In tissue culture of the organ of Corti, the hair cells which were supported by many kinds of supporting cells were maintained for more than 20 DAE. On the contrary in the isolated hair cell culture the single hair cell layer or single hair cells which were separated from its supporting cells degenerated in short time. Most simple reasons for these findings might be the followings (1) the hair cells which are separated from their supporting cells are easily damaged mechanically during the procedure of cultivation especially by the pressure of the cellophane strip (2) generally in tissue culture the duration of survival depends greatly on the size of the tissue explanted Larger pieces of tissue tend to survive better than smaller ones and smaller pieces of tissue are again usually more viable than isolated cells. It is possible that in general, the isolated hair cells may be difficult to be maintained in vitro But the isolated Hensen s cells can survive and grow Therefore the isolated hair cells may have some weakness of their own In case of the hair cells of the atrophy type in this experiment, it can be explained by the reason of (1) for their membrane was damaged, as was detected by the Erythrocin B staining. However the swelling type of them is difficult to be explained by only the reason of (1), because the membrane was intact in outline, and even in case that a single hair cell was perfectly protected from the direct pressure of the cellophane strip in the ample space beside large tissue masses, the hair cell swelled and degenerated easily And so it follows necessarily that these findings mentioned above can not be explained by only the reasons of (1) and (2), it should be discussed on the standpoint of the correlation between the hair cells and the supporting cells Originally the inner and outer hair cells are connected with the supporting cells the inner limiting cells, the inner phalanges, the inner and outer rods, De ter s cells, Hensen s cells and cells of Claudius It is easy to consider that the hair cells are mechanically protected by the supporting cells from any kinds of damages in addition to supporting the structure Besides, from the present data, it may be possible to say that the hair cells and the supporting cells have some functional connections concerning the nutritional requirement and cell metabolism

In case of the isolated hair cell culture, the reticular lamina and the auditory hair showed no changes under phase-contrast microscopical observation during the short time after explantation when the hair cell himself had swollen, ruptured and degenerated Also in case of the culture of the organ of Corti as a whole no irregularity was noticed in the reticular frame work for about 1 to 2 DAE when most of the hair cells swelled more or less. Up to now many investigators have chosen the reticular frame work as the degenerating sign of the hair cells by phase-contrast microscopical observations. This is correct only in case of chronic changes of the hair cells And so it is necessary to pay attention when the acute change of the hair cells is observed

The granular materials in the cytoplasm had some active movement in the fibroblast and the outgrow epithelial cell These movements depend on the physiological flow of the cytoplasm and it might be considered as a sign of "living" for these cells. On the other hand, no granular move-

ments were observed in the cytoplasm of the hair cells when they were intact and actively living. However the extensive granular movements like "Brownian movement" appeared when the cell membrane of the hair cells was already damaged more or less such as in the atrophy mentioned above or the swelling type at the maximal swelling. The following can be thought: Originally the cytoplasm of the hair cells is so-called "gel" condition and it has no granular movement. By the change of the permeability of membrane according to the damage of cells, the cytoplasm changes from "gel" to "sol" and the unphysiological granular movement like "Brownian movement" appears. So, in other words, it can be said that the granular movements in the cytoplasm is a sign of the membrane damage in case of the hair cells.

In this experiment, the outer hair cells were easily affected by the changes of circumstances in culture than the inner when the organ of Corti cultivated as a whole. Much greater differences are found in the behavior pattern of both hair cells in other experimental conditions. EFFECT OF DIFFERENT VESTIBULAR LESIONS UPON BODY EQUILIBRIUM FUNCTION IN SQUIRREL MONKEYS

Makoto Igarashi and Yuko Kato[1]

From Baylor College of Medicine, Houston, Texas, USA

Abstract. By utilizing the squirrel monkey rail test, postoperative compensation status after unilateral saccular macula destruction, unilateral utricular nerve section and unilateral lateral ampullary nerve section, were studied in a quantitative fashion and the results were statistically compared. First, it was confirmed that the preoperative random assignments of subjects were evenly distributed among different experimental categories and therefore inter-categoric statistical comparisons of postoperative status were valid. Minimal effect after the unilateral saccular macula ablation toward the maintenance of body equilibrium was reconfirmed. The utricular input is probably the most important for the maintenance of body equilibrium function, inasmuch as slightly less equilibrium disturbance was found after unilateral lateral ampullary nerve cut even though the difference was not significant.

After partial ablation of the peripheral labyrinthine end organ, the condition of body dysequilibrium changes dynamically. Thus, it is important to study the body equilibrium function along the time course which represents systemic imbalance and eventual compensation from disturbances occurring within the system. Thus, any investigation of equilibrium function conducted only at one fixed time has only limited merit.

Quantitative comparisons of the compensation of the body equilibrium function along the time span will demonstrate the relative importance of the different parts of the vestibular end organ system in locomotive body equilibrium function and recovery from injury or loss of part of the system. Histological confirmation should be performed in all experimental and sham subjects in order to correlate the extent of ablation to the disturbances in performances and to recovery. The importance of this morphological confirmation has been recognized in the past especially after surgically created lesions.

By utilizing partial ablation procedure in different experimental animal species, the contribution from the different vestibular end organs to body equilibrium function has been investigated by Versteegh (1927), and McNally & Tait (1933), McNally & Stuart (1942), Jongkees & Philipszoon (1964), Mair & Fernandez (1966), Igarashi (1968, 1970), Igarashi et al. (1970), Igarashi & Miyata (1972), Igarashi et al. (1972) and others.

The purpose of the present communication is to demonstrate the difference in the effect after selective unilateral retrenchment of macula sacculi, maculi utriculi, or lateral ampullary nerve in the squirrel monkey. Inter-categorical comparisons were performed statistically.

METHOD AND PROCEDURE

Subjects

The subjects used in the present experimental series were South American squirrel monkeys (Saimiri sciureus). Originally they were from Colombia and quarantined in the Miami, Florida area before being sent to our vivarium in Houston, Texas. They were healthy young adults, about two years old, and with no preference as to their sex. Their body weights ranged from 550 to 700 grams. The acquisition of these

EFFECT OF DIFFERENT VESTIBULAR LESIONS UPON BODY EQUILIBRIUM FUNCTION IN SQUIRREL MONKEYS

Makoto Igarashi and Yuho Kato[1]

From Baylor College of Medicine Houston, Texas, USA

Abstract. By utilizing the squirrel monkey rail test, post operative compensation status after unilateral saccular macula destruction, unilateral utricular nerve section and unilateral lateral ampullary nerve section, were studied in a quantitative fashion and the results were statistically compared. First, it was confirmed that the preoperative random assignments of subjects were evenly distributed among different experimental categories and therefore inter-categoric statistical comparisons of postoperative status were valid. Minimal effect after the unilateral saccular macula ablation toward the maintenance of body equilibrium was reconfirmed. The utricular input is probably the most important for the maintenance of body equilibrium function, inasmuch as slightly less equilibrium disturbance was found after unilateral lateral ampullary nerve cut even though the difference was not significant.

After partial ablation of the peripheral labyrinthine end organ, the condition of body dysequilibrium changes dynamically. Thus, it is important to study the body equilibrium function along the time course which represents systemic imbalance and eventual compensation from disturbances occurring within the system. Thus, any investigation of equilibrium function conducted only at one fixed time has only limited merit.

Quantitative comparisons of the compensation of the body equilibrium function along the time span will demonstrate the relative importance of the different parts of the vestibular end organ system in locomotive body equilibrium function and recovery from injury or loss of part of the system. Histological confirmation should be performed in all experimental and sham subjects in order to correlate the extent of ablation to the disturbances in performances and to recovery. The importance of this morphological confirmation has been recognized in the past especially after surgically created lesions.

By utilizing partial ablation procedure in different experimental animal species, the contribution from the different vestibular end organs to body equilibrium function has been investigated by Versteegh (1927), and McNally & Tait (1933), McNally & Stuart (1942), Jongkees & Philipszoon (1964), Mair & Fernandez (1966), Igarashi (1968, 1970), Igarashi et al. (1970), Igarashi & Miyata (1972), Igarashi et al. (1972) and others.

The purpose of the present communication is to demonstrate the difference in the effect after selective unilateral retrenchment of macula sacculi, maculi utriculi, or lateral ampullary nerve in the squirrel monkey. Inter-categorical comparisons were performed statistically.

METHOD AND PROCEDURE

Subjects

The subjects used in the present experimental series were South American squirrel monkeys (Saimiri sciureus). Originally they were from Colombia and quarantined in the Miami Florida area before being sent to our vivarium in Houston, Texas. They were healthy young adults, about two years old, and with no preference as to their sex. Their body weights ranged from 550 to 700 grams. The acquisition of these

This study was supported by grants NS-07237, 1 PO1 NS-10940, and 5-K03-NS-34619.

[1] In collaboration with Joel K. Levy B.A., Charles H. Bowden, B.A., and John C. Ledet, MEE.

experimental subjects was made at many different times over several years and therefore, the subjects belonged to randomly different original batches. The animals were acclimated to be fed Purina Monkey Chow some fruits, and water which contained vitamin complex. A pair of animals were housed in a 75 cm cubicle metal cage with ordinary room lighting and air ventilation. Room temperature was maintained at 76 to 80°F with desirable humidity

Apparatus

The rail test apparatus which was described by Igarashi in 1968 consists of a shuttle avoidance situation with a rotating rail positioned between the two shuttle end compartments (Fig. 1). The rail is cross-sectionally X-shaped (3 8 cm × 3 8 cm), and the entire length is 180 cm. This rail can be rotated along its longitudinal axis at a speed up to 1000 rpm without any danger The rotating rail is centered in a cylindrical enclosure, which is 180 cm in length and 150 cm in diameter (positioned horizontally). The rotating rail is positioned parallel to the longitudinal axis of the cylinder

The shuttle compartments (30 cm × 30 cm 40 cm) of plexiglass are stationarily mounted to th end of the cylinder so that the subject can proceed from one shuttle end box, across the rail to the opposite shuttle end box

During the training and testing procedure the entire apparatus is covered with a heavy black velvet cloth, with small peep holes. The conditioned stimulus (CS) is the darkening of an incandescent bulb o er the occupied shuttle compartment and the simultaneous illumination of an identical light over the unoccupied box The unconditioned stimulus (UCS) is a scrambled manually viable intensity electric shock produced by a Foringer 1154-M11 shock power

supply and fed through a Foringer 1925 grid shock scrambler to 6 mm diameter stainless steel bars which comprise the floor of the shuttle compartment, and also underlie the rotating rail. The rail is not electrified but can be rotated continuously so that it is impossible for the subject to remain on it. The CS-UCS interval is two seconds (timed by a Lehigh 1309 timer), and the intertrial interval is 20 seconds (timed by a Grason-Stadler E4300 timer).

Both the CS and the UCS are continuous after presentation. Two Foringer 1186-M1 sequence coordinators are used to switch the light and electric shock between the two shuttle compartments.

Screening and training

Squirrel monkeys were screened to eliminate unsuitable subjects for this conditioning experiment, such as those which responded improperly to the rail test apparatus. These include continuous random activity, freezing to electrified grids, etc. Ample time was given to let naive subjects explore the entire apparatus before starting the screening procedure. During this screening maneuver, stimulus presentation was manually controlled. The rail speed was manually adjusted for each subject (usually below 90 rpm) according to its behavior and ability to maintain equilibrium function. Usually 30–60 trials (CS-UCS presentations) were given in a single block.

The basic training period consisted of the presentation of about six blocks of about 60 trials each, so that the avoidance rail-running response would become reflexive. Subjects simultaneously received conditioning and physical practice at low speed (200 rpm) rail running. When a subject fell or jumped off the rail, the rail was stopped in order to let the subject climb back onto it.

Pre-operative threshold measurement

This stage is concerned with determining the highest speed of rail rotation at which the subject could no longer traverse the rail without falling off. The present rail test device can provide the maximum of 1000 rpm speed without any danger to either the subject or the examiner.

Initially the rail rotating speed was set at 0 rpm. If the subject successfully crossed it, the speed was increased in increments of 50 rpm after each successful traversing until the speed of 1000 rpm was reached, or until the subject made four consecutive unsuccessful attempts of traversing the rail at any certain given rpm. This rpm value was defined as the subject's "threshold of dysequilibrium". When the subject fell, the rail was immediately stopped in order to let him climb back up on it, and subsequently reach the safe shuttle box. Usually the CS-UCS interval was 2 seconds and the intertrial interval remained at 20 seconds during this test procedure. No signs of fatigue were found even after testing at high rpm levels.

Surgery

Experimental categories in the present series are saccular macula destruction (S), utricular nerve section (U), and lateral ampullary nerve section (L). All surgical procedures were performed unilaterally under aseptic conditions. Intraperitoneal injection of sodium pentobarbital (30 mg/kg) was used for general anesthesia. A retroauricular atticotomy approach was used and the major part of the surgery was performed under the operating microscope. After retracting the external acoustic meatus skin and tympanic membrane anteriorly, the postero-superior edge of the bony external meatus wall was partly removed by a small angled curette. The incus was removed after subluxating the incudo-stapedial articulation with a fine pick. The stapedial tendon was divided and the annular ligament of the stapes was separated all around the stapedial base by a very fine pick. Attempts were made to remove the stapes in toto; however, some were removed in a piecemeal fashion. Intense movement of perilymph was strictly avoided during this procedure. The anterior inferior edge of the vestibular fenestra was drilled off very little to acquire a better view of the entire saccular macula. The saccular membrane was ruptured and a fine pick was inserted to

experimental subjects was made at many different times over several years and, therefore, the subjects belonged to randomly different original batches. The animals were acclimated to be fed Purina Monkey Chow some fruits, and water which contained vitamin complex. A pair of animals were housed in a 75 cm cubicle metal cage with ordinary room lighting and air ventilation. Room temperature was maintained at 76 to 80 F with desirable humidity

Apparatus

The rail test apparatus which was described by Igarashi in 1968 consists of a shuttle avoidance situation with a rotating rail positioned between the two shuttle end compartments (Fig. 1) The rail is cross-sectionally X shaped (3 8 cm × 3 8 cm), and the entire length is 180 cm. This rail can be rotated along its longitudinal axis at a speed up to 1000 rpm without any danger The rotating rail is centered in a cylindrical enclosure which is 180 cm in length and 150 cm in diameter (positioned horizontally) The rotating rail is positioned parallel to the longitudinal axis of the cylinder

The shuttle compartments (30 cm 30 cm × 40 cm) of plexiglass are stationarily mounted to the end of the cylinder so that the subject can proceed from one shuttle end box, across the rail to the opposite shuttle end box

During the training and testing procedure the entire apparatus is covered with a heavy black velvet cloth, with small peep holes The conditioned stimulus (CS) is the darkening of an incandescent bulb over the occupied shuttle compartment and the simultaneous illumination of an identical light over the unoccupied box The unconditioned stimulus (UCS) is a scrambled manually viable intensity electric shock produced by a Foringer 1154-M11 shock power

Fig. 2 Photomicrograph demonstrates horizontal-sectional view of the five day postablative condition of the area of the macula sacculi in squirrel monkey. Notice the saccular space is almost occupied by the connective tissue (large arrow). Some ossification (O) can be noticed already. Also tight closure of the utriculo-endolymphatic fold (F) can be seen. H & E staining. 97

indicated that these means were not significantly different, $F\ (2, 18) < 1$. It was thus confirmed that randomly assigned squirrel monkeys were evenly distributed among different experimental categories as far as the equilibrium function is concerned. Therefore, the postoperative inter categoric data analysis could be assumed to relate observations of comparably treated subjects.

The number of calendar and trial days each

destroy the saccular macula. The rupture and dislodgement of the statoconia had to be ensured during this procedure so that the saccular macula carried no more gravito-inertial receptor function The use of aspiration was minimized during this entire procedure except for removing bone dust and blood Thereafter the vestibular fenestra was sealed by autogenous adipose graft which was kept in place by gelfoam in the tympanic cavity Seven squirrel monkeys belonged *to this category*

For the group of unilateral utricular nerve section the antero-superior edge of the vestibular fenestra was very slightly drilled off after the stapes was removed, in order to obtain a better visualization of the utricular macula and nerve An extremely fine and sharp pick was used to section the utricular nerve along the bony wall After sectioning the nerve, slight bleeding was usually noticed Seven subjects which belonged to this category were used for the subsequent statistical evaluation.

To approach the lateral ampullary nerve the horizontal portion of the facial nerve was exposed by opening the bony canal. When it was necessary the latero-posterior portion of the geniculate ganglion was removed Then, the superior posterior bony wall of the geniculate ganglion was gently drilled to expose the lateral ampullary nerve An extremely fine pick was used to cut the nerve. Seven monkeys with successful 75–100 % nerve section were processed for statistical analysis.

Postoperative threshold measurement

The procedure of the postoperative rail threshold testing was identical to that of preoperation Animals were continuously tested until their rail thresholds reached the preoperative level for a minimum of three consecutive trial days.

Morphology

Upon the completion of acquisition of functional data, all animals were sacrificed by means of intravital cardiac perfusion. Temporal bones were removed and processed according to the standard preparation technique Serial horizontal *sections were made at 20 micron thickness*, one out ten sections were stained in hematoxylin-eosin, and examined by light microscopy

Statistics

For the statistical analysis, the following were used (1) the number of trial days of basic training, and threshold testing days to reach the operable criterion (three consecutive trial days with the rail threshold of 1 000 rpm or a given rpm more than 900 rpm plateau, with a minimal number of falls during one test sequence), and (2) the number of trial days and calendar days before the subject regained the preoperative rail threshold level for the first time postoperatively The purpose of statistical analysis is twofold, namely (1) to confirm that the randomly assigned subjects were evenly distributed among different experimental categories, and (2) to compare the effect of selective ablation among three experimental categories postoperatively

RESULTS

The mean number of trial days to reach the operative criterion was 14 6 for S 15 4 for U" and 15 7 for L An analysis of variance

Table I

"S	Trial days	Calendar days	U"	Trial days	Calendar days	L	Trial days	Calendar days
A	3	3	H	8	10	O	5	7
B	3	3	I	9	11	P	4	9
C		2	J	5	9	Q	6	8
[illegible]	4	4	K	6	11	[illegible]	6	8
[illegible]	4	4	L	1	14	[illegible]	11	17
F	3	3	M	18	21	T	5	9
G	3	3	N	11	13	U	12	16
$\bar{x}$	3 14	3 14		9.84	12.71		7.00	10.57

on postoperative trial days. While the results of this test approached significance ($F\ (2, 18) = 2.982$, $p < 0.1$), the Duncan's test clarified the relationship between the treatments, and demonstrated significant differences between the treatment mean of "S" and "U" and "L" ($p < 0.05$). Also, no significant difference could be detected between "U" and "L" with regard to trial days.

Subsequent morphological investigation confirmed the destruction of the target end organs (Figs. 2, 3) and nerves (Fig. 4). Also other vestibular end organs in sound ears were not involved morphologically. The extent of the surgical lesions within each experimental group was found to be slightly variable among different subjects, but the difference was minimal. All inner ear end organ structures of the other ears

Fig 3 A and B Photomicrographs show the inferior portion of the macula utriculi (*U*) from the unoperated ear (*A*) and the utricular nerve sectioned ear (*B*) from the same subject. The neurons are degenerated, and many vacuole formations in the maculi utriculi can be seen 17 days postoperation. Horizontal section, H & E staining. (*A*) 77 (*B*)

subject required to regain the preoperative rail threshold level is given in Table I

An analysis of variance on postoperative calendar days yielded a significant $F(2, 18) = 15.72$, $p < 0.01$ Duncan's multiple range test showed that the number of calendar days to regain the level of preoperative criterion was significantly less for subjects in "S" than for subjects in either "U" or "L" ($p < 0.001$) No significant difference was found between "U" and "L"

Another analysis of variance was performed

degrees of postoperative labyrinthine reaction had to be expected. However as far as the body equilibrium *compensation* is concerned, the difference which was caused by surgical maneuver can be considered to be minimal as long as the present rail test, which measures the subject's maximum ability of locomotion performance, is being used for functional measurement. Such a difference may be manifested if a more sensitive measurement maneuver is used.

The contribution from the lateral crista ampullaris toward the maintenance of body equilibrium function was reconfirmed, by comparing the unilateral lateral ampullary nerve section and the unilateral utricular nerve section group. The difference between these two groups was not significant. However the trend demonstrated the longer compensation time after utricular nerve section, when compared to that after the lateral ampullary nerve section.

After unilateral utricular nerve section, the monkey has a systemic imbalance caused by the ablation of spontaneous discharge. In addition, the animal is deprived of unilateral utricular input (during his locomotive performance) which has a definite role in assisting the body equilibrium maintenance. Similar deprivation of the saccular input, if it is contributing toward the body equilibrium maintenance, should be considered. After unilateral lateral ampullary nerve section, in addition to the ablation-resulted systemic imbalance, the animal also suffers from the existence of horizontal beating postoperative nystagmus which biases his visual equilibrium cue, and also changes from time to time because of the oculomotor compensation along the time course. Also the inner ear was not opened by this operation procedure and therefore there should not be any direct labyrinthine reaction. Thus, in a strict analytical sense, the quantitative comparison of ablative effect of these two vestibular end organs by the present behavioral functional measurement has certain limitations due to the above described coexisting factors. However in a bionomical synthetical sense, these postoperative status represent the different postablative systemic dysequilibrium.

ZUSAMMENFASSUNG

Unter Anwendung des früher beschriebenen Schienenversuchs mit Totenkopfaffen wurde der Zustand nach der Operation von einseitiger sacculärer Macula Entfernung, einseitiger utriculärer Nervensektion und einer einseitigen Quersektion des ampullären Nerven vergleichsweise bewertet und statistisch verglichen.

Durch ein statistisches Verfahren wurde gleichfalls bestätigt, dass die freie Wahl von Subjekten gleichmässig verteilt war unter verschiedenen Versuchskategorien und daher war der entsprechende kategorisch-statistische Vergleich des Zustandes nach der Operation gültig.

Der minimale Beitrag der sacculären Macula zur Unterhaltung des körperlichen Gleichgewichtes wurde wieder bestätigt. In so weit wie das gegenwärtige Versuchsverfahren angewandt wird, wurde nur ein sehr wenig geringer dominierender Beitrag der lateralen Crista ampullaris gefunden im Vergleich mit dem Beitrag der utriculären Macula, begründet auf den unter sich kategorischen Vergleich, obwohl der Unterschied statistisch nicht bedeutend war. Die utriculäre Macula ist wahrscheinlich das wichtigste vestibuläre Endorgan zur Erhaltung der körperlichen Gleichgewichtsfunktion.

in all experimental subjects were found to be morphologically intact

DISCUSSION

The results of postoperative intercategoric comparisons of "S" vs U and S" vs. L" indicate that the analysis of calendar day means demonstrates a clearer and statistically significant difference when compared against means of trial days The number of calendar days should be used for this sort of analysis (i e between experimental groups) insofar as the body equilibrium compensation requires a certain length of time inherent to the lesion probably regardless of the number of trials during that time period

Previously the minimal body dysequilibrium (locomotive) in squirrel monkeys was reported after unilateral saccular macula destruction when the body equilibrium function was measured the squirrel monkey rail test (Igarashi 197 Stepwise experimental controls, which includ routine stapedectomy and the saccular me brane rupture demonstrated minimal surgic involvement by these procedures A subseque report demonstrated severe locomotive dysequ librium after the unilateral utricular nerve sectic without exception (Igarashi et al 197?) E utilizing scattergraphs, the difference in boc equilibrium compensation after unilateral utri ular nerve section and unilateral saccul macula destruction was demonstrated In th present study by using a statistical procedure a significant difference between these two experi mental categories was well documented

The extent of surgical lesions was slightly varied among different subjects because of ana tomical and surgical variability Also different

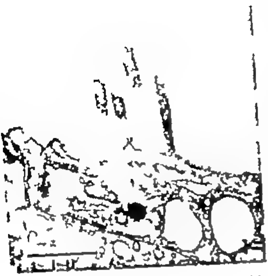

Fig. 1. Sensory hairs are present in most hair cells of the ampulla.

formed to section the saccular nerve to complete the saccular nerve section, the route through the oval window was selected. Although total hearing loss resulted, his dizziness attacks disappeared.

MATERIALS AND METHODS

The approach to the inner ear was through the suprafacial root. The bony wall was thinned by the drill and opened by the chisel. The lateral and the anterior ampullae and the utricle were exposed. Those were removed by a cupforceps.

The tissue fragments obtained were immediately fixed in 6.25 glutaraldehyde solution with phosphate buffer (pH 7.4) at 4 C for 90 min. Then, the specimens were briefly rinsed with phosphate buffer (pH 7.4) at 4 C, and post-fixed in 1 osmic acid with phosphate buffer for 90 min. After dehydration with graded alcohol and acetone, the materials were embedded in Epon 812. The polymerized Epon blocks of the specimens were sectioned on a glass knife with a Porter Blum Ultramicrotome. The sections were stained with uranyl acetate and lead citrate and examined with a Hitachi HU-11E electron microscope with a magnification range of 1300 to 27 000.

RESULTS

The light microscopic examination revealed that the specimens removed during surgery were the utricle and ampullae. The ampullae were anterior and horizontal, but it was not determined which ampulla was horizontal. The utricle was confirmed by the presence of the otolithic membrane.

Under electron microscopic examination, type I type II hair cells and supporting cells were observed in the sensory epithelium. Most of the hair cells of the macula utriculi and crista ampullaris retained sensory hairs (Fig. 1), and a few hair cells were observed not to have sensory hairs. The remaining hairs were rising either straight or bent. Most hair cells showed normal subcellular structures (Figs. 2, 3*a* and 3*c*).

The mitochondria appeared healthy. There were some hair cells, however with vacuoles in the cytoplasm (Figs. 2 and 3*b*). Fig. 2 illustrates a healthy type I hair cell showing a synaptic bar and a pathologic type I hair cell with vacuoles and dark inclusions. The dark inclusions were considered to be lipofuscin granules. Lipofuscin was found distributed in most hair cells, supporting cells, transitional cells and dark cells. Nerve endings and fibers did not contain lipofuscin. The lipofuscin was localized around the subsurface areas of the supporting cells and in the supranuclear portions of type I and type II hair cells.

The nerve chalices had a normal structure and the mitochondria were not pathological (Figs. 2 and 3). Besides the synaptic bodies, synaptic invaginations and thickening of the synaptic membranes were observed (Fig. 3*c*). The efferent nerve endings were seen to synapse with the nerve chalice (Fig. 3*d*). The nerve endings contained many healthy mitochondria.

The hair cells with pathologies like vacuoles or shrinkage of the cytoplasm were sparsely distributed throughout the sensory epithelia. The distribution of the pathological hair cells in the utricle was more general than in the ampullae. Cytoplasmic protrusion of the supporting cells was a common finding in both utricle and ampullae.

ELECTRON MICROSCOPIC OBSERVATIONS OF THE UTRICLE AND AMPULLAE IN A CASE OF DIZZINESS OF SUSPECTED SACCULAR ORIGIN

Tetsuo Ishii and Jun-Ichi Suzuki

From the Department of Otolaryngology Teikyo University School of Medicine Tokyo, Japan

Abstract Electron microscopic observation was reported on the utricle and ampullae of a case, a 36-year-old male, with dizziness attack due to suspected saccular origin. After the removal of the utricle and ampullae, the dizziness recurred, and finally the saccular nerve section relieved the dizziness attack of this case. So the actual lesion was localized in the saccule and was not in the specimens obtained at the first surgery Though most of hair cells appeared normal, there were a few with many vacuoles or shrinkage of the cytoplasm distributing sparsely throughout the sensory epithelia. The distribution of the pathological hair cells in the utricle was more general than in the ampullae. The sensory hair cells without pathology and the presynaptic structures were similar to those found in the experimental animals. Nerve and nerve endings showed normal structures. The findings may be physiological at this age group or an extension of the pathology of the dizziness-causing lesion.

Electron microscopic studies of human vestibular labyrinth have been done on specimens obtained either from cadavers or from patients who had undergone surgery for Ménière s disease. In the previous paper (Suzuki et al 1974), a case of suspected sacculogenic dizziness was reported This patient a 36-year-old male, complained of repeated dizziness attacks with tinnitus. The patient underwent three times selective ablation of the labyrinthine endorgans. After saccular nerve section the dizziness terminated During the first operation the utricle and ampullae were removed and the specimens were extended to the electron microscopic evaluation The purpose of the present paper is to report the electron microscopic findings in the vestibular labyrinth of the case and to correlate the morphology to the clinical diagnosis. It should be noted that the specimens did not include the saccule which were believed to be the location of the lesion.

This work was partly supported by U.S.P.H.S. Research Grant No. NS 1041-

CASE REPORT

A 36-year-old male visited our clinic with a complaint of frequent attacks of dizziness and tinnitus in the right ear His dizziness was vibratory in the vertical direction and was always accompanied by tinnitus. These attacks began four years prior to his admission. A slight hearing loss on the right was found Calorization revealed a decreased response on that side. Although equilibrium disturbances were slight, there was some falling tendency to the right Under Frenzel glasses, a fine direction-fixed positional and positioning nystagmus was seen directed to the left On the basis of the neurological examinations, and also from the fact that Xylocaine application into the right tympanic cavity temporarily abolished the dizziness and tinnitus, an operation was performed on the right inner ear The utricle and two ampullae were removed via the supra-facial route and the specimens were examined with an electron microscope

The patient was relieved from the dizziness attacks and the hearing was restored The recurrence of the dizziness began gradually a month and a half after the first operation A second surgical procedure was the saccular nerve section through the supra-facial route which was not successful, the dizziness reappearing one week after surgery One month after the second operation, the third operation was per

Fig. 1. Sensory hairs are present in most hair cells of the ampulla.

formed to section the saccular nerve. To complete the saccular nerve section, the route through the oval window was selected. Although total hearing loss resulted, his dizziness attacks disappeared.

MATERIALS AND METHODS

The approach to the inner ear was through the suprafacial root. The bony wall was thinned by the drill and opened by the chisel. The lateral and the anterior ampullae and the utricle were exposed. Those were removed by a cupforceps.

The tissue fragments obtained were immediately fixed in 6.25 % glutaraldehyde solution with phosphate buffer (pH 7.4) at 4°C for 90 min. Then, the specimens were briefly rinsed with phosphate buffer (pH 7.4) at 4°C, and post-fixed in 1% osmic acid with phosphate buffer for 90 min. After dehydration with graded alcohol and acetone, the materials were embedded in Epon 812. The polymerized Epon blocks of the specimens were sectioned on a glass knife with a Porter Blum Ultramicrotome. The sections were stained with uranyl acetate and lead citrate and examined with a Hitachi HU-11E electron microscope with a magnification range of ×1300 to 27 000.

RESULTS

The light microscopic examination revealed that the specimens removed during surgery were the utricle and ampullae. The ampullae were anterior and horizontal, but it was not determined which ampulla was horizontal. The utricle was confirmed by the presence of the otolithic membrane.

Under electron microscopic examination, type I, type II hair cells and supporting cells were observed in the sensory epithelium. Most of the hair cells of the macula utriculi and crista ampullaris retained sensory hairs (Fig. 1), and a few hair cells were observed not to have sensory hairs. The remaining hairs were rising either straight or bent. Most hair cells showed normal subcellular structures (Figs. 2, 3a and 3c).

The mitochondria appeared healthy. There were some hair cells, however, with vacuoles in the cytoplasm (Figs. 2 and 3b). Fig. 2 illustrates a healthy type I hair cell showing a synaptic bar and a pathologic type I hair cell with vacuoles and dark inclusions. The dark inclusions were considered to be lipofuscin granules. Lipofuscin was found distributed in most hair cells, supporting cells, transitional cells and dark cells. Nerve endings and fibers did not contain lipofuscin. The lipofuscin was localized around the subsurface areas of the supporting cells and in the supranuclear portions of type I and type II hair cells.

The nerve chalices had a normal structure and the mitochondria were not pathological (Figs. 2 and 3). Besides the synaptic bodies, synaptic invaginations and thickening of the synaptic membranes were observed (Fig. 3c). The efferent nerve endings were seen to synapse with the nerve chalice (Fig. 3). The nerve endings contained many healthy mitochondria.

The hair cells with pathologies like vacuoles or shrinkage of the cytoplasm were sparsely distributed throughout the sensory epithelia. The distribution of the pathological hair cells in the utricle was more general than in the ampullae. Cytoplasmic protrusion of the supporting cells was a common finding in both utricle and ampullae.

Fig 2 Type I hair cells of the ampulla. The hair cell on the left looks normal, while on the right vacuoles and dark inclusions (lipofuscin) are observed. *C* Chal *SB* synaptic bar

In Fig. 4 a type II hair cell is shown from the crista ampullaris. The cytoplasm of the hair cell contained a few vacuoles, and the thicken ing of the synaptic membranes was observed. Mitochondria of the nerve endings appeared normal. Some of these nerve endings showed healthy synaptic vesicles.

The nerve fibers consisted mostly of myelinated fibers and these showed normal structures (Fig. 5*a*). Some of the nerve fibers were found to show minor pathologies (Fig. 5*b*) These changes consisted of shrinkage of the axoplasm swollen mitochondria in the axon and disorganization of the myelin There was no abundant loss of fibers Degeneration of the axon was rarely found In places, some banded structures were present in the perineural tissues (*Fig. 5b*).

The dark cells showed marked cytoplasmic protrusions. Various kinds of vacuoles were seen in the subsurface areas. These dark cells also showed an electron-dense cytoplasm at the base they formed complicated cytop mic infoldings (Fig. 6) Huge lipofuscin grani were observed within the cells. Some of th were localized within large vacuoles (Fig. These lipofuscin granules consisted of 3 differ types, i.e. highly electron-dense small granu structure less electron-dense amorphous str tures and lipid like droplets (Fig 6) Th seemed to be no pattern in the distribution these granules within the cell

DISCUSSION

In this particular case extensive vacuolizati was not found which was usually observed the hair cells of Ménière s disease (Pietranto & Iurato 1960 Litton & Lawrence 1961 Ir land & Farkashidy 1963 Hilding & Hous

Fig. 3. Type I hair cells of ampulla. (*a*) A normal type I cell. There are no mitochondrial changes. (*b*) Hair cells with vacuolization distribute sparsely in the sensory epithelium. (*c*) Synaptic invaginations. (*d*) Two efferent nerve endings (*E*) attach to the chalice (*C*). *H* Type I hair cell.

1964; Friedmann et al., 1963 and 1965). This case did, however, show a diffuse scattering of hair cells that had less extensive vacuolization within the cytoplasm. Considering that dizziness attacks disappeared after saccular nerve sectioning, the lesion was assumed to be in the saccule. The authors, therefore, did not expect causative lesion in the utricle and ampullae. These findings are interpreted in two ways. The morphological findings of the utricle and ampullae are explained to be within the normal physiological limits of this age group. Another interpretation is that these findings in the utricle and ampullae are an extension of the pathology of the dizziness-causing lesion in the saccule.

The utricular and ampullary nerves appeared normal and the nerve endings showed intact structures. Presynaptic structures in the human inner ear were exactly the same as reported in the experimental animals. There were synaptic invaginations, synaptic bodies and thickened synaptic membranes. Though some of fibers were seen to show a mild degenerating pattern, this may be due to physiological aging (Bergström, 1973).

The banded structures, found in the peri-

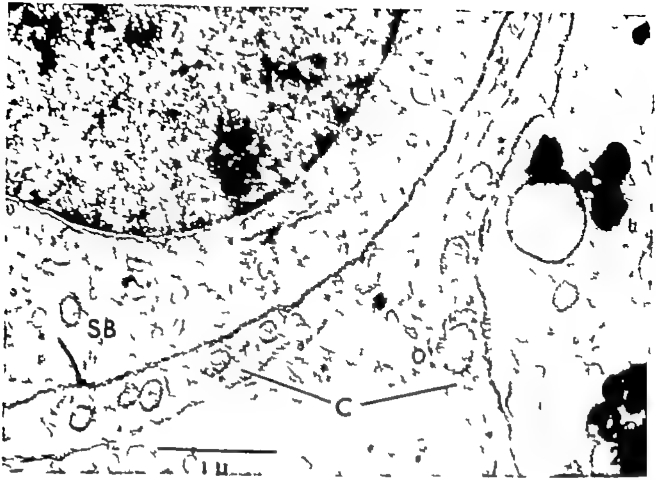

Fig. Type I hair cells of the ampulla. The hair cell on the left looks normal, while on the right vacuoles and dark inclusions (lipofuscin) are observed. *C*, Chalice. *SB*, synaptic bar.

In Fig. 4 a type II hair cell is shown from the crista ampullaris. The cytoplasm of the hair cell contained a few vacuoles, and the thickening of the synaptic membranes was observed. Mitochondria of the nerve endings appeared normal. Some of these nerve endings showed healthy synaptic vesicles.

The nerve fibers consisted mostly of myelinated fibers and these showed normal structures (Fig. 5*a*). Some of the nerve fibers were found to show minor pathologies (Fig. 5*b*). These changes consisted of shrinkage of the axoplasm, swollen mitochondria in the axon and disorganization of the myelin. There was no abundant loss of fibers. Degeneration of the axon was rarely found. In places, some banded structures were present in the perineural tissues (Fig. 5*b*).

The dark cells showed marked cytoplasmic protrusions. Various kinds of vacuoles were seen in the subsurface areas. These dark cells also showed an electron-dense cytoplasm and at the base they formed complicated cytoplasmic infoldings (Fig. 6). Huge lipofuscin granules were observed within the cells. Some of them were localized within large vacuoles (Fig. 6). These lipofuscin granules consisted of 3 different types, i.e. highly electron-dense small granular structure, less electron-dense amorphous structures and lipid-like droplets (Fig. 6). There seemed to be no pattern in the distribution of these granules within the cell.

DISCUSSION

In this particular case extensive vacuolization was not found, which was usually observed in the hair cells of Ménière's disease (Pietrantoni & Iurato, 1960; Litton & Lawrence, 1961; Ireland & Farkashidy, 1963; Hilding & House

Fig. 3. Type I hair cells of ampulla. (*a*) A normal type I cell. There are no mitochondrial changes. (*b*) Hair cells with vacuolization distribute sparsely in the sensory epithelium. (*c*) Synaptic invaginations. (*d*) Two efferent nerve endings (*E*) attach to the chalice (*C*). *H* Type I hair cell.

1964; Friedmann et al., 1963 and 1965). This case did, however, show a diffuse scattering of hair cells that had less extensive vacuolization within the cytoplasm. Considering that dizziness attacks disappeared after saccular nerve sectioning, the lesion was assumed to be in the saccule. The authors, therefore, did not expect causative lesion in the utricle and ampullae. These findings are interpreted in two ways. The morphological findings of the utricle and ampullae are explained to be within the normal physiological limits of this age group. Another interpretation is that these findings in the utricle and ampullae are an extension of the pathology of the dizziness-causing lesion in the saccule.

The utricular and ampullary nerves appeared normal and the nerve endings showed intact structures. Presynaptic structures in the human inner ear were exactly the same as reported in the experimental animals. There were synaptic invaginations, synaptic bodies and thickened synaptic membranes. Though some of fibers were seen to show a mild degenerating pattern, this may be due to physiological aging (Bergström, 1973).

The banded structures, found in the peri-

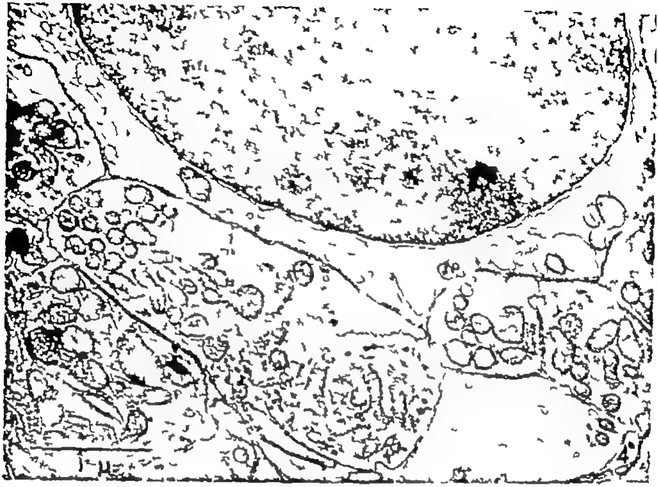

Fig 4 Several nerve endings contact with the type II hair cell. Thickened areas of synapses are observed. The mitochondria and synaptic vesicles of the nerve endings are preserved well, while vacuoles are seen in the cytoplasm of the hair cell.

neural tissues, were already reported from inner ear specimens of Ménière s disease (Hilding & House, 1964 Friedmann et al 1963 and 1965 Kimura & Schuknecht 1970) These structures possibly were not related to the pathology of Ménière s disease

In the reports of Ménière s disease, the most common findings were loss of sensory hairs, extensive vacuolization of hair cells, the presence of dark inclusions and well-preserved nerve endings A hypothesis attempting to explain the mechanism of vertiginous attacks cited the presence of pathological hair cells in normal cyto-neural junctions (Pietrantoni & Iurato, 1960) Since the dark inclusions were known to exist in the membranous labyrinth of cadavers (Kimura et al 1964 Takahashi 1971), the inclusions were identified as lipofuscin, an age-dependent, "wear and tear" pigment (Ishii et al., 1967). This lipofuscin was not found in the inner ear of 2-day-old baby but it began to appear in 6-year-old child and was increasing in size and number according as ages (Ishii et al., 1967).

In the inner ear of the present case (36-year old) a considerable amount of lipofuscin was present The fact that this lipofuscin was found in the dark cells indicates that the dark cells perform an active secretory and/or absorptive function and are filled with vesicles and lysosomes. Lipofuscin is thought to be the final stage of a lysosome. The inner ear is presumed to provide an environment where the lipofuscin easily accumulates.

Fig. 5. Most nerve fibers show good myelination here in the ampullary nerve (*a*), but shrinkage of axoplasm and mitochondrial swelling in the axon in some portion of the utricular nerve fibers (*b*). Banded structures are seen in the perineural tissues.

Fig. 6. The dark cells contain huge vacuoles [illegible] which are considered to be lipofuscin. Cytoplasmic infolds [illegible] varying form of dark inclusions are observed. All of these [illegible] are seen (arrows).

ZUSAMMENFASSUNG

Die elektronenmikroskopische Beobachtung des Utriculus und der Ampullen eines 36-jährigen Mannes, der vom Schwindel belastet ist dessen Ursprung von einer sacculären Schädigung stammt, wurde vorgelegt.

Zwei Monate nach der Resektion des Utriculus und der Ampullen brach der Schwindelanfall wieder aus. Schliesslich trat eine Besserung durch die Resektion des Sacculus ein, auf die Klage des Patienten hin. Die aktuelle Läsion wurde dabei im Sacculus lokalisiert, sie war im Material bei erstem Eingriff nicht bemerkt worden.

Obwohl der grosste Teil der Haarzellen normal erschien, gab es eine Minderzahl von Haarzellen mit vielen Vakuolen oder zytoplasmatischer Einschränkung, die im sensorischen Epithel einzeln verstreut waren. Die Ausstreuung dieser pathologischen Haarzellen kamen im Utriculus häufiger vor als in den Ampullen. Die sensorischen Haarzellen ohne Pathologie und prasynaptische Struktur hatten Ähnlichkeit mit den Haarzellen, die bei Tieren experimentell gefunden wurden Die Nerven und Nervenendigungen zeigten normale Struktur Solche Befunde in dieser Altersgruppe könnten physiologischer oder als den Schwindel hervorrufenden Läsion von pathologischer Art sein.

ACKNOWLEDGEMENT

The authors wish to express their thanks to Mr D W Hughes for his advice on the English language.

DIE LÄSION DES VERTIKALEN SYSTEMS UND DIE LÄSION DES HORIZONTALEN SYSTEMS IM OPTOKINETISCH VESTIBULÄREN SYSTEM

Eiji Sakata und Kunio Takahashi

Aus der Hals-Nasen-Ohrenklinik des Krankenhauses, Tokio-Rosai, Tokio, Japan

Abstrakt. Eine Betrachtung der Symptome von Schwindel und Gleichgewichtsstörung, wie sie bei einer Läsion des optokinetisch-vestibulären Systems auftreten, ließ bei getrennter Betrachtung der Läsion des vertikalen Systems und der des horizontalen Systems erkennen, daß die zu beobachtenden Symptome sich ziemlich einheitlich ordnen lassen. Im ersteren Fall liegt nämlich die Läsion im Zentrum des Hirnstammes bzw. des Kleinhirns oder symmetrisch bzw. beiderseitig des peripher-vestibulären Systems, oder aber sie tritt diffus auf. Im Gegensatz dazu tritt sie im letzteren Fall bei den obigen Stellen einseitig rechts oder einseitig links auf. Die Läsion des vertikalen Systems ergibt sich, daß das optokinetisch-vestibuläre System direkt oder indirekt beiderseitig lädiert ist, und ausgelöst von Schwindel und Gleichgewichtsstörungen, die verspürt werden, und die in Augen sowie *Extremitäten und Kopf auftretenden Symptome* symmetrisch sind äußern sich hauptsächlich auf der Ebene des Systems des vertikalen semicirculären Kanals (der sagittalen Ebene). Im Gegensatz dazu ist es bei Läsionen des horizontalen Systems die Regel, daß sich die Symptome auf der Ebene des horizontalen semicirculären Kanals äußern.

Bei der Diagnose von Patienten, die sich über Schwindel oder Gleichgewichtsstörungen beklagen, wurde bis jetzt das Hauptaugenmerk darauf gerichtet, in welchem Organ das Übel positioniert ist, wie z. B. Hirnstamm oder Kleinhirn, VIII. Nerv oder aber Endorgan des Innenohres. Vom Standpunkt der klinischen Diagnostik her gesehen ist dies eine äußerst bedeutsame Tatsache.

Auf der anderen Seite bestand allerdings bisher die Tendenz, daß bei Untersuchung und Befund *nicht nur bei den subjektiven Symptomen*, sondern auch bei den Symptomen, die in den Augen oder in den Extremitäten auftreten, je nach Fall separat und voneinander unabhängig Beobachtungen gemacht wurden, und *daher nicht unbedingt* genügende Beachtung einer Reihe von Wechselbeziehungen geschenkt wurde, die im Verborgenen zwischen den einzelnen Untersuchungen bestehen. *So wurde oft*, auch nach gefällter Diagnose, keine systematische Analyse der Gesamtheit der aufgetretenen Symptome vorgenommen, und auch der Weiterentwicklung der Diagnostik ein ungewolltes Hindernis in den Weg gestellt.

Wenn wir nun die Sache einmal von einem *etwas anderen Standpunkt aus betrachten, d. h.* von den verschiedenen Symptomen aus, die bei den Fällen von Schwindel oder Gleichgewichtsstörungen beobachtet werden, können in Verbindung mit dem Problem, ob die Läsion des optokinetisch-vestibulären Systems zentral ist oder aber peripher gestört ist, je nachdem ob die *Läsion einseitig oder beidseitig ist*, bei dem entsprechenden Befund der Untersuchung eine Reihe von Besonderheiten beobachtet werden, *die sich ziemlich einheitlich klassifizieren lassen.* Mit anderen Worten, ganz gleich, ob das Übel zentral oder peripher gelagert ist — im Fall einer beidseitigen Läsion z. B. sind die Symptome einander sehr ähnlich.

DIE LÄSION DES VERTIKALEN SYSTEMS UND DIE LÄSION DES HORIZONTALEN SYSTEMS

Als Läsion des horizontalen Systems haben wir solche Fälle angenommen, wo bei einer Läsion des optokinetisch-vestibulären Systems das Übel

Diese Abhandlung soll dem sehr verehrten Professor Dr. Dr. h.c. Tadashi Fukuda anläßlich seines Abschieds von seinem Amte herzlich gewidmet sein.

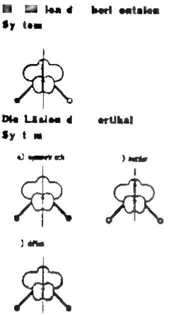

Abb 1 Die Klassifikation der Läsionen.

einseitig auf einer von beiden Seiten positioniert ist.

Die Läsion des vertikalen Systems ist dagegen gegeben, wenn eine Mehrzahl von Läsionen rechts-links-symmetrisch zur gleichen Zeit oder rechts und links diffus oder buchstäblich im mittleren Teil existiert wo das optokinetisch-vestibuläre System ob nun direkt oder indirekt, beidseitig beeinflußt wird (Abb 1)

RESULTATE UND ÜBERLEGUNGEN

Wenn wir zunächst einmal die subjektiven Symptome bei der horizontalen Läsion unter suchen d. h bei einseitigem Befallensein des Innenohrs (z. B Morbus Ménière oder Labyrint hentzündung) oder Akustikustumor im Früh stadium weiterhin bei Arten von Krankheiten des Kleinhirns oder Hirnstammes (wie z. B Blutung der Kleinhirnhemisphäre oder Wallen bergsches Syndrom) erscheint der Schwindel auf der frontalen Ebene oder der horizontalen Ebene der Schwindel dreht sich im Uhrzeiger sinn oder im Gegenuhrzeigersinn man selbst oder die Umgebung fließt nach links oder rechts. Dagegen ist es bei Läsion des vertikalen Systems (z. B plötzlicher Durchblutungsläsion der Arteria basilaris oder vaskuläre Läsion des Kleinhirnwurms) nicht selten daß der Schwindel sich um die sagittale Ebene, d h vor oder zurück, dreht oder Schwankungen nach oben oder unten gefühlt werden. Nervensymptome, wie Kopfschmerz u a., sind bei der Läsion des vertikalen Systems symmetrisch während sie bei der des horizontalen Systems einseitig verlaufen (Tabelle I)

Nun möchten wir unsere Überlegungen auf die objektiven Symptome die in den Extremitäten und im Rumpf auftreten, ausdehnen

Bei der Läsion der vertikalen Systems ist allgemein eine Gleichgewichtsstörung zu beobachten die sich hauptsächlich nach vorwärts- oder in rückwärtiger Richtung auswirkt, wie ich falle nach vorne oder ich falle rückwärts" Mit anderen Worten ist dies eine Gleichgewichtsstörung hauptsächlich der sagittalen Ebene die eine enge Beziehung zur Ebene des vertikalen semicircularen Kanals aufweist. Auch die Ataxie tritt beidseitig auf und in der Regel sind die Läsion von Reflex und Sensibilität ferner auch das Nachlassen der Muskelkraft, beidseitig. Verglichen dazu äußert sich bei der Läsion des horizontalen Systems die Gleichgewichtsstörung im wesentlichen seitwärts, und Ataxie wie auch die Läsion von Reflex und Sensibilität und muskuläre Hypotonie treten einseitig auf (Tabelle II)

Als nächstes möchten wir eine Untersuchung der Symptome die im optokinetisch-vestibulären System zu beobachten sind vornehmen

Bei der Läsion des vertikalen Systems tritt

Tabelle I *Die subjektiven Symptome*

Symptom	Läsion Vertikales System	Horizontales System
Schwindel	Hauptsächlich in der sagittalen Ebene drehen	Hauptsächlich in der frontalen Ebene drehen
Gleichgewichtsstörung	Hauptsächlich in der sagittalen Ebene	Hauptsächlich in der frontalen Ebene
Andere Nervensymptome	Mehr symmetrisch mittler	Mehr einseitig

nicht selten ein vertikaler Spontannystagmus nach dem oberen Augenlid bzw. nach dem unteren Augenlid auf. Verglichen dazu ist es bei der Läsion des horizontalen Systems die Regel, daß ein horizontaler Spontannystagmus, bzw. ein horizontalrotierender gemischter Spontannystagmus beobachtet wird (Frenzel, 1955; Kornhuber, 1966; Sakata, 1966). Auch bei Betrachtung des Lagenystagmus und Lagerungsnystagmus zeigt sich, daß bei der Läsion des vertikalen Systems häufig ein vertikaler Lagenystagmus oder Lagerungsnystagmus zu beobachten sind, und ferner ein richtungswechselnder aufwärtschlägiger Lagenystagmus (bei Bewegung des Kopfes des Patienten nach rechts unten wird es ein Nystagmus nach links, bei Bewegung nach links unten wird es ein Nystagmus nach rechts) festzustellen ist, dagegen ist bei Läsion des horizontalen Systems ein richtungsbestimmter Lagenystagmus zu beobachten (Sakata, 1966, 1971). Auch ist, besonders bei einseitigen Innenohren-Fällen, nicht selten ein den Schwindel begleitender rein rotierender Lagenystagmus und ferner ein rein rotierender gegenläufiger Lagerungsnystagmus zu beobachten (Stenger, 1955; Sakata u. a., 1966). Der blickabhängige Nystagmus ist bei der Läsion des vertikalen Systems, sei es nun ein paretischer Nystagmus, der von einer Läsion des Hirnstammes herrührt, oder ein dysmetrischer Nystagmus, der auf Grund einer Läsion des Kleinhirnes auftritt, oder aber eine Läsion, die auf einer Fixationsstörung wie idiopathischem kongenitalem Nystagmus beruht, mehr oder weniger rechts-links-symmetrisch. Im Vergleich dazu ist er bei einer Läsion des horizontalen Systems immer einseitig und unsymmetrisch (Tabelle III).

Tabelle II. *Die Symptome an dem Rumpf und den Extremitäten*

Symptom	Läsion: Vertikales System	Läsion: Horizontales System
Gleichgewichtsstörung	Hauptsächlich in der sagittalen Ebene (nach vorne bzw. hinten)	Hauptsächlich in der frontalen Ebene (nach seitlich fallen bzw. deviieren)
Ataxie	Hauptsächlich beiderseitig	Hauptsächlich einseitig
Reflex, Sensibilität, Muskelkraft usw.	Hauptsächlich beiderseitig	Hauptsächlich einseitig

Tabelle III. *Der Nystagmus*

Nystagmus	Läsion: Vertikales System	Läsion: Horizontales System
Spontannystagmus	Vertikal od. schräg	Horizontal od. horizontal-rotierend
Lagenystagmus	Vertikal, schräg, oder richtungswechselnd aufwärts-schlägig	Richtungsbestimmt
Lagerungsnystagmus	Vertikal	Horizontal, horizontal-rotierend od. rein-rotierend u. gegenläufig
Blicknystagmus	Symmetrisch blickparetisch blickdysmetrisch	Asymmetrisch od. manchmal einseitig

Ferner möchten wir die motorische Störung betrachten, die bei den Augen hervorgerufen wird.

Was die konjugierte Blickbewegung angeht, so wird durch Läsion des Hirnstammes, besonders der des Pons, die horizontale Blickbewegung gestört, während bei Läsion des Mittelhirns hauptsächlich die vertikale Blickbewegung gestört wird. Es ist gezeigt worden (Bender et al., 1964; Sakata et al., 1971), daß im ersteren Fall die Läsion der paramedianen Brückenhaube (paramedian pontine tegmentum), im letzteren eher die Läsion von Hinterkommissur und Pretectum als die des Colliculus superior einen großen Einfluß haben. In solchen Fällen ist im ersteren wie im letzteren Fall die sog. „schnelle Augenbewegung" wie die schnelle Phase des Nystagmus oder die sakkadierende Augenbewegung etc., empfindlicher gegen diese Läsionen, kann in einem früheren Stadium Störungen empfangen als die „langsame Augenbewegung" wie die Blickfolgebewegung oder

Tabelle IV *Die andere Bewegungsstörung an den Augen*

Befund	Läsion Vertikales System	Horizontales System
Blick	Vertikal	Horizontal
Optokinetischer Nystagmus	Beiderseitig symmetrisch	Einseitig asymmetrisch
Optokinetischer Nachnystagmus	Bei Kleinhirn verlängert. Bei Hirnstamm od. periph. vest. gehemmt	Seitendifferenz
Blickfolge	Symmetrisch	Asymmetrisch. Bei periph. vest. normal

die tonische Abweichung, und erholt sich sich auch langsamer als diese

Daher ist es auch bei Prüfung des optokinetischen Nystagmus so daß bei Läsion des vertikalen Systems die Störung beidseitig und symmetrisch erfolgt, während sie bei Läsion des horizontalen Systems (bei Läsion von Innenohr oder Kleinhirn selbst tritt so leicht keine starke Störung auf bei Läsion des Hirnstammes dagegen treten sehr deutliche Störungen auf) einseitig und unsymmetrisch erfolgt Bei Läsion des vertikalen Systems besonders bei Läsion des oberen Hirnstammes (Mittelhirn) wird der optokinetische Nystagmus nach dem oberen Augenlid, bei Läsion des mittleren Hirnstammes (Pons) oder des unteren Hirnstammes (Medulla) wird der optokinetische Nystagmus nach dem unteren Augenlid gestört.

Auch beim optokinetischen Nachnystagmus haben wir fast die gleiche Situation bei Läsion des vertikalen Systems fällt eine deutliche beidseitige Hemmung auf bei Läsion des horizontalen Systems fällt eine links-rechts-Differenz auf während bei Läsion des Kleinhirns zeigt sie eine Überreaktion wegen Ausfalls der Hemmung auf das optokinetisch-vestibuläre System

Auch bei der Blickverfolgungsprüfung ist sie bei Läsion des vertikalen Systems symmetrisch, bei Läsion des horizontalen Systems fällt sie unsymmetrisch aus (bei peripher vestibulärer Störung tritt keine Läsion auf). Darüber hinaus, bei Läsion des Hirnstammes ist sie sakkadierend, bei Läsion des Kleinhirnes treten infolge von Hypermetrie und Hypometrie große Wellen auf (Sakata, 1973) (Tabelle IV)

MUSTERFÄLLE

A Beispiele für Läsion des vertikalen Systemes

Fall 1 K.J 61 Jahre männl Art dextromanuell

Hauptsymptome Kopfschmerzen, Schwindel, Schwächegefühl an Gliedern Gleichgewichtsstörung.

Familiengeschichte Von Hypertonie und Apoplexie belastet.

Anamnese Vor 25 Jahren Pneumonie seit 20 Jahren leidet er unter Hypertonie.

Status praesens Seit ungefähr 10 Jahren leidet er manchmal, hauptsächlich am frühen Morgen unter plötzlichen heftigen Hinterkopfschmerzen *Drehschwindel in der sagittalen* Ebene Brechreiz, Erbrechen, Lähmungsgefühl und Schmerz an beiden Armen. Die Häufigkeit dieses Anfalls 4–5 mal jährlich. Besonders bei *einem Anfall vor 6 Jahren wurde der allgemeine* Krampf mit obengenannten Anfällen begleitet, und der Tremor an den beiden Armen dauerte etwa eine Woche lang.

Vom 4 oder 5 Monat an nach diesem Anfall vor 6 Jahren, wankte er oft *vorwärts oder rückwärts* und allmählich wurde sein Gang gestört Eine Zeitlang danach bekam er Anfälle jedoch nicht so oft aber seit etwa zwei Jahren tritt der Anfall wider auf Ein blutdrucksenkendes Mittel und Krampfmittel wurden eingenommen doch wurde die Krankheit nicht besser Vor drei Monaten bekam er einen ziemlich heftigen Anfall und dabei entdeckte sein Freund ein Arzt, den Nystagmus.

Prüfungsresultate Blutdruck 165–112. Augenhintergrund, K–W II Grad. Die beiderseitigen leichten Stauungspapillen sind erkennbar In aufgerichteter Haltung fällt der Patient beim

Augenschließen leicht nach hinten. Beim Tretversuch hat er eine Falltendenz vor- und rückwärts. Kein Kleinhirnsymptom. Auch kein Hirnnervensymptom. Der Sehnenreflex steigert sich beiderseitig ein bißchen. Kein pathologischer Reflex ist sichtbar. Der zerebrospinale Druck und dessen Eigenschaft sind normal.

Wenn der Patient ohne Brille nach vorne sieht, ist der kurzperiodisch, unregelmäßig *richtungsalternierende horizontale* Nystagmus erkennbar. Beim Auf- und Niederblick wird dieser Nystagmus ein *vertikaler* Nystagmus in Unteraugenlidrichtung, beim Blick nach rechts und links wird er ein Nystagmus in der *rechten* und *linken* Blickrichtung, und in beiden Fällen ist keine Veränderung der Richtung zu erkennen. Bei Benutzung der Leuchtbrille ist kein Nystagmus erkennbar. Bei der Lageprüfung ist der richtungsalternierende aufwärtsschlägige Nystagmus festzustellen, und auch bei der Kopfhängelage wird ein *vertikaler* Nystagmus ausgelöst. Bei der Lagerungsprüfung ist ein feinschlägiger *vertikaler* Nystagmus sichtbar. *Aber dabei klagte* der Patient gleichzeitig über *ein* starkes Schwindelgefühl. Die beiderseitige Entziehungshemmung des optokinetischen Nystagmus. Die Motorik der Blickzielverfolgung ist *symmetrisch* ziemlich gestört.

In CAG und VAG ist keine bemerkenswerte Veränderung sichtbar, aber bei PEG befindet sich ein symmetrisches Vergrößerungsbild der beiderseitigen Gehirnkammer und des Ventriculus tertius. Durch die Myodil-Ventrikulographie ist ein Befund, der vielleicht als leichter Schattendefekt im *hinteren* Bereich des Ventriculus quartus zu betrachten ist, erhältlich.

Operationsbefunde: Da auch der Patient es wünschte, wurde die Kraniotomie durchgeführt. In der Kleinhirnhemisphäre wurde keine außergewöhnliche Veränderung festgestellt, aber *im Wurm* wurde die Atrophie betrachtet und besonders im Unterwurm war schon deren Spur vorhanden. Jedoch im Bereich des Oberwurms über Mittelwurm war ein außergewöhnlicher Vorwölbungsteil sichtbar. *Durch die Punktion* wurde ca. 1,5 cc gelbe Flüssigkeit aspiriert. Beim ... war ein kleines Blutgerinnsel *er*kennbar. Die Cystis wurde *mit physiologischer* Kochsalzlösung genug gespült *und* ein Teil der inneren Wand experimentell exzidiert. Pathohistologisch war *kein Befund* des Haemoangioms feststellbar.

Betrachtung: *Bei* diesem Fall wurde der Anfall langperiodisch wiederholt. Es ist offensichtlich, daß zwischen diesen Anfällen und den pathologischen Veränderungen am Wurm irgendeine Beziehung besteht. Es scheint mir, daß es eine enge Kausalität mindestens zwischen dem Anfall vor drei Monaten und dieser krankhaften Veränderung des Wurms, ferner dem eigenartigen Nystagmus, gibt. Aber ich kann leider nicht zu einer Folgerung gelangen, ob das Atrophiebild, das im ganzen Wurm betrachtet wurde, mit den lange wiederholten Anfällen zusammenhängt, oder ob diese Atrophie ein sogenanntes „Degenerationszeichen" ist und die Ursache dualistisch erklärt werden *soll*.

Fall 2: I.I., 54 Jahre, weiblich, Hausfrau, dextromanuell

Hauptsymptome: Schwankschwindel, Ataxie nach vor- *und rückwärts*, Gangstörung, Ohrensausen re. <li. und Schwerhörigkeit bds.

Familiengeschichte: Nichts Besonderes.

Anamnese: Geburt 5mal, Abortus 2mal, vor 35 Jahren Keratoparenchymatose.

Status praesens: Seit etwa 2 Jahren ist Ataxie vorhanden. Ihr Gang wird allmählich gestört, und sie wankt leicht *vorwärts oder rückwärts*. Vor 4 Monaten hatte sie plötzlich einen Schwindelanfall, der etwa 3 Stunden anhielt und von Übelkeit und Erbrechen begleitet wurde. Danach wurden die Gangstörungen deutlicher und *beidseitiges* Ohrensausen *und* Schwerhörigkeit traten auf. Von einem *Internisten wurde ihr* gesagt, daß Verdacht auf einen *Kleinhirntumor* bestehe.

Hauptresultate der Prüfungen: Blutdruck 154–94, K–W I-Grad, Rombergsches Symptom (++), *fällt vor- oder rückwärts*. Bei der Mannschen *Prüfung* zeigt sie starke Schwankungen, mit uneinheitlicher Fallrichtung. Kann nicht auf Zehenspitzen oder Fersen laufen. Beim Tretversuch *hat sie rückwärtige* Falltendenz. Wasser

Tabelle IV *Die andere Bewegungsstörung an den Augen*

	Läsion	
Befund	Vertikales System	Horizontales System
Blick	Vertikal	Horizontal
Optokinetischer Nystagmus	Beiderseitig symmetrisch	Einseitig asymmetrisch
Optokinetischer Nachnystagmus	Bei Kleinhirn verlängert. Bei Hirnstamm od. periph. vest. gehemmt	Seitendifferenz
Blickfolge	Symmetrisch	Asymmetrisch. Bei periph. vest. normal

die tonische Abweichung, und erholt sich sich auch langsamer als diese

Daher ist es auch bei Prüfung des optokinetischen Nystagmus so daß bei Läsion des vertikalen Systems die Störung beidseitig und symmetrisch erfolgt während sie bei Läsion des horizontalen Systems (bei Läsion von Innenohr oder Kleinhirn selbst tritt so leicht keine starke Störung auf bei Läsion des Hirnstammes dagegen treten sehr deutliche Störungen auf) einseitig und unsymmetrisch erfolgt Bei Läsion des vertikalen Systems, besonders bei Läsion des oberen Hirnstammes (Mittelhirn), wird der optokinetische Nystagmus nach dem oberen Augenlid bei Läsion des mittleren Hirnstammes (Pons) oder des unteren Hirnstammes (Medulla) wird der optokinetische Nystagmus nach dem unteren Augenlid gestört

Auch beim optokinetischen Nachnystagmus haben wir fast die gleiche Situation bei Läsion des vertikalen Systems fällt eine deutliche beidseitige Hemmung auf bei Läsion des horizontalen Systems fällt eine links-rechts-Differenz auf während bei Läsion des Kleinhirns zeigt sie eine *Überreaktion* wegen Ausfalls der Hemmung auf das optokinetisch vestibuläre System

Auch bei der Blickverfolgungsprüfung ist sie bei Läsion des vertikalen Systems *symmetrisch* bei Läsion des horizontalen Systems fällt sie unsymmetrisch aus (bei peripher vestibulärer Störung tritt keine Läsion auf) Darüber hinaus, bei Läsion des Hirnstammes ist sie sakkadierend, bei Läsion des Kleinhirnes treten infolge von Hypermetrie und Hypometrie große Wellen auf (Sakata, 1973) (Tabelle IV)

MUSTERFÄLLE

A *Beispiele für Läsion des vertikalen Systemes*

Fall 1 K I 61 Jahre männl Arzt dextromanuell

Hauptsymptome Kopfschmerzen Schwindel Schwächegefühl an Gliedern, Gleichgewichtsstörung.

Familiengeschichte Von Hypertonie und Apoplexie belastet

Anamnese Vor 25 Jahren Pneumonie seit 10 Jahren leidet er unter Hypertonie

Status praesens Seit ungefähr 10 Jahren leidet er manchmal, hauptsächlich am frühen Morgen, unter plötzlichen heftigen Hinterkopfschmerzen, Drehschwindel in der sagittalen Ebene Brechreiz, Erbrechen, Lähmungsgefühl und Schmerz an beiden Armen Die Häufigkeit dieses Anfalls 4–5 mal jährlich Besonders bei einem Anfall vor 6 Jahren wurde der allgemeine Krampf mit obengenannten Anfällen begleitet, und der Tremor an den beiden Armen dauerte etwa eine Woche lang.

Vom 4 oder 5 Monat an nach diesem Anfall vor 6 Jahren wankte er oft *vorwärts oder rückwärts* und allmählich wurde sein Gang gestört Eine Zeitlang danach bekam er Anfälle, jedoch nicht so oft aber seit etwa zwei Jahren tritt der Anfall wider auf Ein blutdrucksenkendes Mittel und Krampfmittel wurden eingenommen, doch wurde die Krankheit nicht besser Vor drei Monaten bekam er einen ziemlich heftigen Anfall, und dabei entdeckte sein Freund ein Arzt, den Nystagmus.

Prüfungsresultate Blutdruck 165–112 Augenhintergrund, K–W II Grad Die beiderseitigen leichten Stauungspapillen sind erkennbar In aufgerichteter Haltung fällt der Patient beim

mann-Bluttest positiv Im linken Ohr besteht Verdacht auf das Hennebertsche Zeichen *Bei* der Calorischen Prüfung fällt *die Reaktion rechts wie links* deutlich ab Auch die kompensatorische Gegenrollung der Augen läßt auf *beiden* Seiten ziemlich nach *Was die Hörschärfe* angeht so zeigt sie auf *beiden Seiten* mittelgradige perzeptive Schwerhörigkeit. *Mittels* der Lagerungsprüfung wurde ein *mehr als* 10maliger *Vertikalnystagmus* nachgewiesen

Betrachtung Dies ist ein Fall bei *dem am* meisten Verdacht auf peripher vestibuläre Läsion auf *beiden* Seiten besteht, im besonderen auf beidseitige Innenohr Läsion alle Symptome zeigen die Eigenschaften der Läsion des vertikalen Systems.

B *Beispiel für Läsion des horizontalen Systems*

Fall 3 A S 23 Jahre männlich Kaufmann dextromanuell

Hauptsymptome *Gangstörung,* Ohrensausen re Sprachstörung und *Handtremor re*

Familiengeschichte und Anamnese Nichts Besonderes.

Status praesens Eine Nacht vor 5 Monaten hatte er einen Krampf am ganzen Körper mit 38 5 C Fieber Einige Tage danach verspürte er bei Körperbewegungen vom *rechten* Occipital zum Parietal hin einen pulsierenden Schmerz. Seit 3 *Monaten* hat er Ohrensausen auf der *rechten* Seite Seit mehreren Wochen fallen Gangstörungen auf und es besteht eine Fall *tendenz nach rechts Sein rechter* Hausschuh fällt vom Fuß oder beim Hinuntersteigen der Treppe strauchelt er auf dem *rechten* Fuß. Es kommt auch vor daß er seine Eßstäbchen, die er in der *rechten* Hand hält fallen läßt.

Hauptresultate der Prüfungen Beim Aufstehen besteht Fallneigung nach *rechts* Kein Einbeinstehen möglich Beim Tretversuch wankt er nach *rechts* Fast keine Stauungspapille vorhanden Sowohl bei Seitenblick links als auch bei Seitenblick rechts ist ein dysmetrischer *horizontaler* Nystagmus zu beobachten Bei der Lageprüfung wird sowohl bei Kopfposition des Patienten nach rechts unten wie auch bei Position *nach links* unten ein horizontaler Nystagmus hervorgerufen Bei der Lagerungsprüfung ist *ein nach links schräg* unten gerichteter Nystagmus zu beobachten Der optokinetische Nystagmus hat eine Seitendifferenz, er wird *lebhaft nach links* hervorgerufen aber es scheint, in sowohl rechter als linker Richtung, zumindest keine deutliche Läsion des okulomotorischen *Systems* zu bestehen Bei der Blickverfolgungsprüfung kann eine dysmetrische Struktur beobachtet werden. Weder Pyramiden-Symptom, Sensibilitätsstörung noch pathologischer *Reflex sind* vorhanden, der Liquordruck ist im Anfangsdruck 130 H_2O nach Entnahme von 5cc ist der Enddruck 120 H_2O Pandy positiv

Betrachtung Unter Verdacht auf einen Tumor der *rechten* Kleinhirnhemisphäre führten wir VAG und PEG durch Durch Ausführung der Kraniotomie stellten wir ein in der rechten Kleinhirnsphäre einseitig existierendes Astrozytom fest und exzidierten es.

Dies ist ein Beispiel für Läsion des horizontalen *Systems.*

SUMMARY

Symptoms of vestibulo-ocular disturbances may be classified into two major groups i.e., vertical plane and horizontal plane disturbances

Vertical plane symptoms arise from midline lesions of the cerebellum or the brainstem and also from diffuse or symmetrical lesions to either

Vertical plane symptoms also arise from lesions which simultaneously effect both peripheral vestibular systems.

Horizontal plane symptoms originate from a unilateral disturbance in the vestibular system
